

University of Cincinnati

Date: 4/19/2019

I, Elizabeth N Orr, hereby submit this original work as part of the requirements for the degree of Doctor of Philosophy in Geology.

It is entitled:

"Deciphering tectonic and climatic controls on erosion and sediment transfer in the NW Himalaya"

Student's name: **Elizabeth N Orr**

This work and its defense approved by:

Committee chair: Lewis Owen, Ph.D.

Committee member: Richard Beck, Ph.D.

Committee member: Craig Dietsch, Ph.D.

Committee member: Dylan Ward, Ph.D.

Abstract

Central to examining orogenic belt formation and evolution are efforts to define the relative roles of tectonics and climate in landscape denudation, and the complex feedbacks that exist between them. Studies in high altitude, high relief mountain settings such as the Himalayan-Tibetan orogen show that these relationships are not completely straightforward and that denudation can scale with tectonics, precipitation and/or topography. Steep north-south trending gradients in elevation, relief, rock uplift and precipitation make the NW Himalaya an excellent location to examine these controls of landscape denudation.

As a first step to help elucidate the erosional processes involved in sediment mobilization from primary sources at catchment headwaters, rates of lateral rockwall slope erosion are defined for a suite of 12 catchments between the Baltistan region of Pakistan and Garhwal, northern India. These rates are derived from ^{10}Be cosmogenic nuclide concentrations in medial moraine sediment, and affirm that between ~0.02 and 7 m of lateral slope erosion through periglacial processes can be achieved across a single millennium in this setting, and >2 km when extrapolated for the whole Quaternary. This erosion is sufficient to influence topographic change at the catchment head, and emphasizes the importance of localized erosion when evaluating broader landscape change. Statistically significant relationships are apparent between slope erosion and apatite fission track cooling ages and inferred rates of exhumation. The distribution and magnitude of these latter records of denudation are argued to be the result of the Indo-Eurasian convergence and the geometry and shortening of the Main Himalayan Thrust. Rockwall slope erosion in the NW Himalaya is therefore found to be primarily governed by tectonically driven rock uplift, with precipitation as a secondary control.

To examine the nature and timing of sediment transfer from primary sources to transient sinks, such as landforms and sediment deposits, 18 new and 29 recalculated ^{10}Be fan surface exposure ages define the timing of surface abandonment for a suite of 10 fans across the Greater Himalaya ranges in Ladakh, Lahul, Kullu and Garhwal in northern India. The fans are found to evolve during interglacials and periods of deglaciation, which are associated with a higher intensity monsoon. As glacial conditions or periods of relative cooling and increasing aridity become reestablished, aggradation ceases or becomes more restricted and the fan surfaces stabilize and/or are abandoned. A regional temporal framework of landform abandonment/aggradation cessation and incision events for the monsoon-influenced western Himalaya ranges (MWHR) and the semi-arid western Himalaya ranges (SWHR) are defined for the NW Himalaya. The timing of regional landform abandonment events for the MWHR and SWHR is consistent with the fan record, occurring during periods of relative cooling and increasing aridity. Regional incision events are less straightforward as they are recognized across various climatic conditions, likely due to the ubiquitous nature of erosion in these active alpine settings. A preservation bias in favor of Holocene geomorphic evidence in the MWHR is due to elevated rates of erosion in this region, which rapidly rework and overprint landforms and sediment deposits. Lower rates of erosion in the SWHR, assist in the preservation of geomorphic evidence throughout the last glacial. Climate and climate-driven processes largely moderate sediment transfer in the NW Himalaya; however, the distribution of precipitation and temperature are themselves influenced by the structural evolution of the orogen.

Although the primary controls of erosion and sediment transfer in this study are shown to be rock uplift and climate respectively, this research overall argues that the various components of Himalayan mountain range evolution cannot each be governed by one mechanism alone. Instead, the coupling between tectonics and climate is central to examining processes of erosion and sediment transfer in this setting and in evaluating broad trends in landscape change. The specific

nature and rates of landscape change on the catchment scale are shown to be influenced by longstanding catchment-specific feedbacks between topography, geology, surface processes, climate and tectonics, in addition to regional forcings on the mountain range and/or orogen scale. Catchment-wide landscape change can be viewed as a continuum of sediment transfer cycles, which trace sediment from a source to its eventual evacuation from the catchment. Each step within a transfer cycle is moderated by a set of preconditioning factors, and one or more forcing factor. This approach emphasizes the important contribution of preexisting landscape dynamics and variability in external forcings over space and time, in the landscape development of high altitude, high relief mountains ranges of the Himalayan-Tibetan orogen.

‘When we try to pick out anything by itself,
we find it hitched to everything else in the universe’

– *John Muir* (1838–1914)

Acknowledgments

My PhD program, research projects and associated field campaigns have been funded by the Department of Geology at the University of Cincinnati, PRIME Laboratories at Purdue University, National Geographic, the Geological Society of America and the UC Graduate Student Governance Association.

I would like to extend my sincere thanks to my primary advisor Professor Lewis Owen for his invaluable instruction and continued support throughout this process. I would like to acknowledge my committee members, Dr. Dylan Ward, Dr. Craig Dietsch and Dr. Richard Beck who have generously shared their time and expertise with me over the past four years. Heart felt thanks are extended to Sourav Saha for his support, experience and humor in the field and out, and to Sarah Hammer for her instruction and friendship in the Geochronology Laboratories. I would also like to acknowledge Dr. Jeff Havig, Dr. Tom Lowell, Dr. Aaron Diefendorf and Jason Cesta for constructive conversations about research projects and career. Thanks are also extended to Dr. Marc Caffee for comments on iterations of manuscripts. Many thanks to Discover Ladakh Adventure Tours and Travel for providing vital logistical support across three field campaigns.

In my four years at the University of Cincinnati, my path has crossed countless people who have contributed to my research, and professional and personal development (sadly, too many people to mention individually). I would therefore just like to thank the students, postdocs, staff and faculty of the Department of Geology, past and present, for making this process as enjoyable and rewarding as it has been.

Finally, none of this would have been possible without the unwavering support, generosity and patience of my friends and family on either side of the Atlantic Ocean, and my partner. Thank you for putting up with me.

I would like to dedicate this dissertation research to my grandmother – for had she lived in a different time and under different circumstances, she would have done this and more.

1. Introduction

Much attention has been paid to understanding the large-scale coupling between tectonic and climatic processes in the geology and dynamics of orogenic belts and the particular processes that govern smaller-scale landscape development. Central to this field of research are the efforts to evaluate the relative roles of these forcings in landscape denudation, and the feedbacks between them (Willett, 1999; Godard et al., 2006; Whipple and Meade, 2006; Whipple, 2009; Roe and Brandon, 2011). From single grain to orogen scale, landscape denudation has been investigated using techniques of geomorphology, sedimentology, geochemistry, numerical dating and physical and numerical modeling (e.g. DeCelles et al., 2001; Bookhagen et al., 2005; Hobley et al., 2010; Anoop et al., 2012; Egholm et al., 2012; Scherler et al., 2015). Studies have been far from unanimous; denudation in high altitude, high relief settings such as the Himalayan-Tibetan orogen has been shown to scale with tectonics (Burbank et al., 2003; Godard et al., 2014; Scherler et al., 2014), precipitation (Thiede et al., 2004; Grujic et al., 2006; Clift et al., 2008; Gabet et al., 2004; Wulf et al., 2010; Deeken et al., 2011) and/or topography (Vance et al., 2003; Scherler et al., 2011, 2014).

Over recent years, the onset and acceleration of late Cenozoic glaciation in the Himalayan belt is argued to have enhanced landscape denudation through intensified rates of sedimentation and localized incision (Zeitler et al., 2001; Korup and Montgomery, 2008; Owen and Dortch, 2014). However, there is a growing volume of literature that argues that Himalayan landscape change, specifically erosion and sediment transfer is instead governed by tectonically driven rock uplift, and that climate and climate-driven surface processes play an important yet secondary role (Burbank et al., 2003; Thiede and Ehlers, 2013; Scherler et al., 2014).

Steep north-south trending gradients in elevation, relief, rock uplift and precipitation make the NW Himalaya an excellent location to examine the strength of coupling between climate and tectonics, for a particular aspect of landscape change (Bookhagen and Burbank 2006, 2010; Scherler et al., 2011). The aim of this dissertation is to pursue two main lines of enquiry; the first is to improve our understanding of the erosional processes involved in the mobilization of sediment from primary sources at the headwaters of glaciated catchments in the NW Himalaya. The second aim is to investigate the nature and timing of sediment transfer from these primary sources to transient sinks, and discuss the insights that these sinks provide in deciphering the controls of landscape change. The rationale for these studies is to examine some of the insights that catchment scale erosion and sediment transfer processes offer for understanding the broader scale evolution and mass flux of mountain belts such as the Himalayan-Tibetan orogen. The objectives of each study are detailed below:

Focus 1 looks to constrain rates of rockwall slope erosion in the upper Bhagirathi catchment of Garhwal, northern India (Fig. 1). This catchment has a well-defined glacial chronostratigraphy and comprehensive records of past and modern glacier behavior. Rockwall slope erosion is calculated by measuring ^{10}Be cosmogenic nuclide concentrations in medial moraine sediment of Gangotri glacier. An important aim of this focus is to test the feasibility of applying this method in a monsoon-influenced catchment with high background denudation rates, and to develop an appropriate sampling strategy for *Focus 2*. The slope erosion dataset is compared to records of catchment-wide erosion and exhumation to evaluate the extent to which slope erosion may differ to other records of landscape change, which have been averaged across various spatial and temporal scales. Slope erosion rates from this study in upper Bhagirathi, and then published rates from Chhota Shigri in the Lahul Himalaya, northern India (Scherler and Egholm, 2017) and Baltoro in the Central Karakoram, Pakistan (Seong et al., 2009) are compared to catchment

parameters and regional climate records to examine the possible controls of slope erosion in the NW Himalaya.

In *Focus 2*, the aim is to define the distribution and magnitude of rockwall slope erosion in the NW Himalaya, by building upon the work of *Focus 1*. Beryllium-10 concentrations are measured in medial moraine sediment to quantify slope erosion rates for a suite of 12 catchments (Fig. 1). To resolve the primary controls of rockwall slope erosion in the NW Himalaya, the patterns of slope erosion are compared to those in geology, tectonics, climate and topography.

Alluvial/debris-flow fans serve as temporary stores of poorly sorted deposits, which include debris-flow, glaciofluvial, fluvial, lacustrine and aeolian sediment (Ballantyne, 2002a,b; Barnard et al., 2006). Much of this sediment originates from the periglacial realms of the catchments and is therefore moderated by the slopes of the source catchments (Barnard et al., 2004a,b; Nicholas and Quine, 2007). Our understanding of the evolution of these landforms with respect to the wider catchment, and the influence of climate and/or tectonism within these sedimentary systems is incomplete. Well-preserved fans in the NW Himalaya provide an excellent opportunity to assess the controls of fan formation in high-relief mountain settings, as well as evaluate how these controls may vary between areas of contrasting climatic regime. In *Focus 3*, 18 new and 29 recalculated ^{10}Be fan surface exposure ages define the timing of surface abandonment for a suite of 10 fans across the Greater Himalaya ranges between Ladakh and Garhwal in northern India (Fig. 1). These fan surface ages are compared to local and regional climate and glacial records to evaluate the contributions of climate and climate-driven surface processes in the timing of fan aggradation and stabilization in the NW Himalaya, throughout the late Quaternary.

Focus 3 demonstrates that climate-driven processes and glaciation play a significant role in fan development. The aim of *Focus 4* is to determine whether this relationship extends to other

geomorphic records of the NW Himalaya. Existing geomorphic records are compiled to construct a regional temporal framework of landform abandonment/aggradation cessation and incision events for the monsoon-influenced western Himalaya ranges (MWHR) and the semi-arid western Himalaya ranges (SWHR) of the NW Himalaya. A further aim of this focus is to determine whether cycles of these regional geomorphic events are recognized in the western end of the orogen.

2. Regional setting

The Himalayan-Tibetan orogen has formed as the result of continued continental collision and partial subduction between the Indian and Eurasian lithospheric plates, which commenced at ~55 Ma (Searle et al., 1997). In the NW Himalaya, the Indus-Tsangpo Suture Zone marks the collision zone between these continental plates and the northern boundary of the Tethyan Himalaya (Fig.1). Deformation-driven crustal shortening from the early Miocene to the Pleistocene initiated the development of a series of foreland propagating thrust systems that divide the Himalayan lithotectonic units south of the Tethyan Himalaya into the Greater Himalaya crystalline sequence, the Lesser Himalaya sequence, sub-Himalaya and foreland basin (Searle, 1986; Steck et al., 1998; Schlup et al., 2003; Vannay et al., 2004; Thakur et al., 2014). The Greater Himalaya is further divided into two sub-units: the southern Greater Himalaya sequence (GHS-S) and the northern Greater Himalaya sequence (GHS-N; DeCelles et al., 2001; Thiede and Ehlers 2013). Continued crustal shortening and thrust and strike-slip faulting throughout the orogen means that the NW Himalaya remains tectonically active in the present (Hodges et al., 2004; Vannay et al., 2004; Bojar et al., 2005).

Northwest Himalayan climate is primarily governed by two atmospheric systems: the Indian summer monsoon advects moisture from the Indian ocean between late May and September and

the northern hemispheric westerlies, which bring moisture from the Mediterranean, Black and Caspian seas between December and March (Gadgil 2003; Lang and Barros 2004; Wulf et al., 2010; Mölg et al., 2013). The imposing orographic barrier of the Himalaya creates a steep precipitation gradient perpendicular (S–N) to the strike of the mountain belt, which became established during the late Miocene (~8 Ma; Qiang et al., 2001; Liu and Dong, 2013). The northward decline in annual precipitation today falls from ~1500–3000 mm in the Lesser and Greater Himalaya ranges, to <150 mm in the interior of the Tibetan Plateau (TRMM 1998–2005, Bookhagen and Burbank, 2006). Most Greater Himalaya glaciers are large, temperate and melt-dominated, and are fed by monsoonal precipitation (Benn and Owen, 2002; Su and Shi, 2002). Glaciers in the semi-arid Greater and Tethyan Himalaya are usually small (1–10 km²) cold-based sub-polar types: precipitation-sensitive and sublimation-dominated (Benn and Owen, 2002).

The study area for this dissertation extends from the Balistan region in the semi-arid Karakoram of Pakistan to Uttarkhand in the Garhwal Himalaya of northern India (Fig 1). This area encompasses sites from the Ladakh and Zaskar Ranges of Jammu and Kashmir and the Lahul-Spiti and Kullu districts in Himachal Pradesh. The investigated catchments present a broad range of morphologies, ranging from steep relief catchments with narrow floors and fluvial gorges, to broad, gently sloping catchments with wide and cultivated floors. The catchments are predominantly glaciated and preserve glacial, fluvial, paraglacial and periglacial landforms and deposits, which include moraines, mass movements, debris-flow/alluvial fans and cones, fill and strath terraces, and outwash and till deposits (Sharma et al., 2016; Orr et al., 2017, 2018; Saha et al., 2018).

3. Methodology

3.1. Remote sensing and terrain analyses

Geomorphic maps were prepared in the field across three field campaigns and then refined using Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) global digital elevation models (GDEMs; 30-m-resolution), Landsat Enhanced Thematic Mapper Plus (ETM+; 15 m resolution) imagery, Google Earth imagery and published geomorphic and geologic maps. Geomorphic and sedimentological techniques described by Benn and Owen (2002) and Benn and Evans (2010) were employed to identify and differentiate between landforms and sediment deposits. Terrain and hydrological data for the investigated catchments were acquired using Spatial Analyst and 3D Analyst toolboxes in ArcGIS. Equilibrium line altitudes for past and contemporary glaciers were also calculated using these tools, following methods of Osmaston (2005) and Benn et al., (2005). Climatic data (e.g. CRU CL 2.0, TRMM 2B31) was extracted and interpolated for each study area using GIS. Catchment surface temperatures were projected from local weather station data and an adiabatic environmental lapse rate of 7°C/km (Derbyshire et al., 1991; De Scally, 1997; Thayyen et al., 2005; Siddiqui and Maruthi, 2007; Bashir and Rasul, 2010; Pratap et al., 2013; Kattel et al., 2013).

3.2. Sedimentological analyses

Detailed sediment and geomorphic descriptions were made of the landforms and deposits examined in the field. Further sedimentological analysis was conducted at the University of Cincinnati in the Sedimentology and X-Ray Laboratories in the Department of Geology and the Advanced Material Characterization Center (AMCC), in order to elucidate the characteristics and transport histories of sediment from various landforms. These analyses included clast size

(Wentworth, 1922; Allen 1981), shape (Hambrey and Glasser, 2003; Hambrey et al., 2008; Lukas et al., 2013), roundness (Sneed and Folk, 1958; Ballantyne and Benn, 1994), surface weathering (Sheridan and Marshall, 1987; Owen et al., 2003) and sample clay mineralogy (Chenn 1977; Moore and Reynolds, 1997).

3.3. Cosmogenic nuclide analyses

Following the initial interaction of primary cosmic rays with the Earth's atmosphere, a secondary cascade of nuclear particles bombard atomic nuclei in target minerals of rock, regolith and sediment, and cause the accumulation of cosmogenic nuclides (Lal, 1991; Gosse and Philips, 2001; Bierman et al., 2002). This study focuses on the accumulation of ^{10}Be in quartz. Nuclide production in quartz is moderated by latitude, atmospheric pressure and elevation, density of material, depth of sample from the surface, surface erosion, shielding, and temporal changes in geomagnetic strength and solar modulation (Lal, 1991 Uppala et al., 2005; Lifton et al., 2005, 2008; Balco et al., 2008; Martin et al., 2016; Marrero et al., 2016; Lifton, 2016). The ^{10}Be concentrations measured in bedrock or surface boulders provide an inferred age of exposure to cosmic rays (e.g. *Focus 3, 4*). Beryllium-10 concentrations in detrital samples from fluvial catchments can be used to infer time-averaged catchment-wide erosion rates. If there is no inherited ^{10}Be , the concentrations are considered to reflect the mean surface concentrations of the source area and are inversely proportional to the derived erosion rates. In *Focus 1* and *2* rockwall slope erosion is quantified by applying this method to medial moraine sediment.

The extraction of quartz and ^{10}Be sample preparation was conducted at the Geochronology Laboratories at the University of Cincinnati, applying the community standards and chemical procedures of Kohl and Nishiizumi (1992). The $^{10}\text{Be}/^9\text{Be}$ of the samples was measured using accelerator mass spectrometry at the Purdue Rare Isotope Measurement (PRIME) Laboratory at

Purdue University (Sharma et al., 2000). Upon the recommendations of Portenga et al. (2015), native ^9Be was measured in each sample and subtracted from the initial ratios. The ^{10}Be production rates for each catchment were calculated with a revised sea-level high-latitude spallogenic production rate of 4.08 ± 0.23 Be atoms/g/a (Martin et al., 2017; <http://calibration.ice-d.org/>), ^{10}Be half-life of 1.36 Ma (Nishiizumi et al., 2007) and a 30-m-resolution GDEM in MATLAB R2017.a, using methods described in Dortch et al. (2011). The accumulation of ^{10}Be during burial, englacial transport and exhumation of sediment to the glacier surface between rockwall and medial moraine was calculated using the Ward and Anderson (2011) analytical model, and then subtracted from the final ^{10}Be concentrations.

Rockwall slope erosion rates for *Focus 1* and *2* were calculated from the total ^{10}Be concentrations and catchment production rates using methods described in detail by Lal (1991), Granger et al. (1996), Balco et al. (2008), and Dortch (2011). The ^{10}Be boulder exposure ages for *Focus 3* were calculated using the Cosmic Ray Exposure program calculator (CREp) of Martin et al. (2017), using the LSD scaling model (Lifton et al., 2014) with the ERA40 atmospheric model (Uppala et al., 2005) and Lifton VDM 2016 geomagnetic database. Published ^{10}Be ages quoted in *Focus 3* and *4* were recalculated using this calculation scheme.

3.4. Statistical analyses

Statistically significant relationships between ^{10}Be concentrations and catchment matrices were identified using Pearson Moment Correlation Coefficient values. A p-value of <0.01 (at $>99\%$ confidence level) was applied. Principle Component Analysis was then used to identify and discuss the primary controls of slope erosion using the R statistical package (The R Core Team, 2018).

To constrain regional events of landform abandonment/aggradation cessation and incision for the MWHR and SWHR, we constructed cumulative probability density functions using the 'ksdensity' kernel in MATLAB R2017.a. The timing of the regional geomorphic events is reported using the gaussian peak (≥ 3 ages) and the uncertainty by gaussian standard deviation values. Landform abandonment events refer to times of restricted sedimentation where landforms stabilize.

4. Foci summaries

4.1. *Focus 1*: 'Rates of periglacial rockwall slope erosion in the upper Bhagirathi catchment, Garhwal, northern India.'

Methodology: Section 3.1–3.3

Publication status: *in revision*. Submitted to *Earth Surface Processes and Landforms* special issue 'Geomorphic diversity of the Indian sub- continent: Progress and Updates'

Periglacial rockwall slope erosion is defined for the upper Bhagirathi catchment using cosmogenic ^{10}Be concentrations in sediment from ablation-dominated medial moraines on Gangotri glacier. Medial moraine sediment characteristics for the lower $\sim 3\text{km}$ of the ablation zone are broadly similar, despite the discrete origins of each landform. Geomorphic and sedimentological analyses confirm that the moraines are predominately composed of rockfall and avalanche debris mobilized from steep relief bedrock slopes via periglacial weathering processes.

Beryllium-10 concentrations range from 1.1 ± 0.2 to $2.7 \pm 0.3 \times 10^4$ at/g SiO_2 , yielding rockwall slope erosion rates from 2.1 ± 0.4 to 5.3 ± 1.2 mm/a. The ^{10}Be concentrations vary between samples of each moraine and between individual landforms; no relationship is evident between nuclide concentration and proximity of sample location to either a glacier margin or snout. Samples from the stable, centermost moraine of Gangotri glacier have ^{10}Be concentrations that fall within error

of each other and show no evidence of sediment input from discrete sources, and are therefore considered to best reflect rates of slope erosion in upper Bhagirathi. The rates of rockwall slope erosion are sufficient to moderate slope sediment flux, glacier dynamics and the topographic configuration of catchment headwaters. Slope erosion rates in upper Bhagirathi are likely to have varied over space and time, and encompassed shifts in climate, glacier mass balance and seismicity, which each operate across various timescales (10^6 – 10^1 years).

Slope erosion rates exceed the averaged catchment-wide and exhumation rates of Bhagirathi and the Garhwal region, which supports the view that erosion at the headwaters can outpace the wider catchment (Sorkhabi et al., 1996; Searle et al., 1999; Vance et al., 2003; Thiede et al., 2009; Lupker et al., 2012; Thiede and Ehlers 2013; Scherler et al., 2014). The difference in erosion rates is likely because these records refer to landscape change across different temporal and spatial scales; slope erosion is sensitive to short-term local change such as stochastic mass wasting events, which on the catchment scale is not recognized (Yanites et al., 2009; Ward and Anderson, 2011; Willenbring et al., 2013; Sadler and Jerolmack, 2014).

The ^{10}Be concentrations in medial moraine sediment for the upper Bhagirathi catchment and the catchments of Chhota Shigri in Lahul, northern India (Scherler and Egholm, 2017) and Baltoro glacier in Central Karakoram, Pakistan (Seong et al., 2009) show no statistically significant relationship with topography (e.g. catchment area, mean elevation, mean slope, relative relief) or projected catchment temperatures. A tentative relationship lies between annual rainfall and ^{10}Be concentration, where higher rainfall coincides with lower concentrations and therefore higher inferred slope erosion rates. This supports the extensive work on the coupling between precipitation and erosion, where enhanced moisture in the monsoon-influenced Lesser and Greater Himalaya drives more rapid landscape change, compared to the semi-arid interior of the orogen (Thiede et al., 2004; Grujic et al., 2006; Clift et al., 2008; Gabet et al., 2004; Wulf et al.,

2010; Deeken et al., 2011). This relationship is not completely straightforward, as similar ^{10}Be concentrations are shared by samples from semi-arid and monsoon catchments.

Rockwall slope erosion in the three study areas, and more broadly across the NW Himalaya is thought to be governed by individual catchment dynamics that vary across space and time. Developing this dataset further, by including more sites throughout the NW Himalaya will help to decipher the local and regional forcings which contribute to landscape change.

4.2. *Focus 2*: ‘Rockwall slope erosion in the NW Himalaya’

Methodology: Section 3.1, 3.3, 3.4

Publication status: Ready to submit to *Earth Surface Processes and Landforms* (awaiting publishing of *Focus 1*).

The distribution and magnitude of periglacial rockwall slope erosion is defined for 12 catchments in northern India using methods consistent with *Focus 1*. Beryllium-10 concentrations range from $5.3 \pm 0.8 \times 10^4$ to $260.0 \pm 12.5 \times 10^4$ at/g SiO_2 , which yield erosion rates between 0.02 and 7.2 ± 1.1 mm/a. Consistent with the findings of *Focus 1*, no relationship is apparent between nuclide concentration and proximity of sample location to either a glacier margin or snout. Any internal variability in concentrations within the catchments is likely because the medial moraine sediment is poorly mixed and/or has a non-proportional sediment supply that is dominated by stochastic rockfall events (Small et al., 1997; Muzikar, 2008; Ward and Anderson, 2011). Between ~ 0.02 and ~ 7 m of lateral erosion can be achieved in this setting across a single millennia, and >2 km when extrapolated for the whole Quaternary. The magnitude of erosion, particularly in the GHS-S is sufficient to affect the strength of hillslope-glacier coupling, catchment sediment flux, glacier dynamics, and help to set the pace of topographic change at the catchment head.

The rockwall slope erosion records from Garhwal, Kullu, Lahul, Ladakh and Baltistan are combined to create a regional erosion dataset (Seong et al., 2009; Scherler and Egholm 2017; *Focus 1*). Rockwall slope erosion largely outpaces the local catchment-wide erosion rates and exhumation in the NW Himalaya (Dortch et al., 2011; Thiede and Ehlers 2013; Scherler et al., 2014; Dietsch et al., 2015). This demonstrates the importance of accounting for localized erosion (<10¹ km²) and its effects on down-catchment reaches in studies of wider landscape change.

Rockwall slope erosion rates become progressively less rapid with distance north from the Main Central Thrust, into the interior of the orogen. The distribution and magnitude of this erosion is most closely associated with patterns in apatite fission track (AFT) cooling ages, inferred rates of Quaternary exhumation and records of Himalayan denudation and rock uplift (Sorkhabi et al., 1996; Searle et al., 1999; Jain et al., 2000; Schlup et al., 2003, 2011; Thiede et al., 2004, 2005, 2006, 2009; Kristein et al., 2006, 2009; Walia et al., 2008). This suggests that tectonically driven uplift, rather than climate, provides a first order control on patterns of slope erosion. Rockwall slope erosion is therefore argued to be part of the erosional response to uplift, which has resulted from the Indo-Eurasian convergence and the geometry and shortening of the Main Himalayan Thrust. Precipitation is likely to play a secondary role in defining the spatial distribution of erosion. Of the catchment parameters that can be defined in the NW Himalaya with some precision, mean rockwall slope, mean catchment and snowline elevation and mean annual temperature also have statistically significant relationships with the ¹⁰Be concentrations. Other attributes which likely influence slope erosion, yet cannot be accounted for in this study include rockwall lithology and rock strength, seismicity and glacial erosion.

The specific rates of rockwall slope erosion for each catchment are therefore likely to be dictated by longstanding feedbacks between topography, geology, surface processes, climate and tectonics. The relative roles of these parameters in driving erosion are likely to vary across space

and time. This study demonstrates the importance of periglacial slope erosion and localized erosion in understanding wider landscape change of high altitude, high relief mountain ranges.

4.3. *Focus 3: 'Climate driven late Quaternary fan surface abandonment in the NW Himalaya'*

Methodology: Section 3.1–3.3

Publication status: *In press*. GSA Special Paper *'Ice-Age glaciers, water, and wind — Interdisciplinary Quaternary science round the world'* in memory of Stephen C. Porter.

The timing of surface abandonment for ten alluvial/debris-flow fans across contrasting climatic settings in the NW Himalaya of northern India are defined using cosmogenic ^{10}Be surface exposure dating. Debris-flow fans in the Garhwal, Kullu and Lahul regions of the monsoon-influenced Greater Himalaya were largely abandoned during the Mid–Late Holocene. Large alluvial fans and smaller debris-flow fans in the semi-arid Ladakh region of the Greater and Tethyan Himalaya have surface ages which extend throughout the last glacial. A preservation bias favors Holocene ages for fan surfaces in the monsoon-influenced ranges, because elevated rates of erosion in this region rapidly rework and overprint landforms and sediment deposits over timescales of 10^4 – 10^1 years (Gabet et al., 2004; Wulf et al., 2010). The lower rates of landscape change in the semi-arid interior ranges help to preserve a longer fan record (Dietsch et al. 2015; Jonell et al., 2018).

The type, size and morphology of the fans are shown to be influenced by the topography and fluvial channel behaviors of the source catchments and trunk valleys. With the exception of the Karzok fans in the Ladakh region, the timing of fan abandonment throughout the NW Himalaya coincides with periods of relative cooling and increasing aridity (Fleitmann et al., 2003, 2007; Wang et al., 2005; Herzschuh et al., 2006; Leipe et al., 2004; Rawat et al., 2015). During warm, wet conditions, fans aggrade and evolve as sediment is released and then transferred throughout the catchments. As the climate then transitions to cooler and drier conditions, aggradation ceases

or becomes more restricted, and the fan surface stabilizes. The exposure ages for each fan also coincide with one or more local glacial stages and between one and five regional glacial stages (Dortch et al., 2013; Murari et al., 2014; Owen and Dortch, 2014; Saha et al., 2018). This study proposes that fans evolve during interglacial periods or phases of deglaciation during a higher intensity monsoon, and then as glacial conditions become reestablished, the fans stabilize.

The interaction between climate and internal catchment dynamics such as geology, topography and sediment supply is shown to dictate the nature and timing of fan evolution and abandonment in the NW Himalaya. Climate-driven processes and glaciation are considered to be important factors in fan sedimentation, catchment sediment flux and the topographic evolution of the NW Himalaya during the late Quaternary.

4.4. *Focus 4: 'Defining controls of regional geomorphic change in the NW Himalaya'*

Methodology: Section 3.3, 3.4

Publication status: *In press*. GSA Special Paper 'Ice-Age glaciers, water, and wind — Interdisciplinary Quaternary science round the world' in memory of Stephen C. Porter.

Regional landform abandonment/aggradation cessation and incision events for the MWHR (monsoon western Himalayan ranges) and SWHR (semi-arid western Himalayan ranges) are defined by a compilation of 206 recalculated ^{10}Be surface exposure ages from fan, and fill and strath terrace surfaces. Records of landform abandonment are recognized in the MWHR region throughout the past ~50 ka with regional events at 1.4 ± 0.5 and 0.6 ± 0.2 ka. Records of incision extend from ~70 to 0.6 ka, with regional incision events at 6.9 ± 3.7 , 3.6 ± 1.0 , 1.8 ± 0.6 and 1.0 ± 0.1 ka. In the SWHR region records of landform abandonment extend over the past 56 ka and >110 ka. Regional events occur at 31.5 ± 5.1 and 20.0 ± 5.3 ka. Records of incision are recognized throughout the past ~120 ka, with events at 35.9 ± 5.8 , 13.7 ± 3.9 and 2.2 ± 1.7 ka. This record

demonstrates a similar preservation bias to *Focus 3*, where records of geomorphic change in landscapes with rapid background denudation rates are restricted to the Holocene.

Regional landform abandonment events largely occur during periods of weakening monsoon strength and cooling, and local and regional glacier advances. Regional incision events from the MWHR and SWHR regions are recognized across various climatic conditions due to the ubiquitous nature of erosion in mountain settings. The most significant regional incision event for both the MWHR and SWHR regions occur at the time of extensive glaciation at the onset of the Holocene. This incision event likely reflects enhanced glacial and fluvial erosion during this glaciation and its associated phase of deglaciation. More broadly, these regional records of geomorphic change illustrate the importance of climate and climate-driven surface processes in landscape change throughout the NW Himalaya.

5. Discussion

5.1. Controls of landscape change

The aim of this dissertation has been to take steps to decipher the primary controls of select processes of erosion and sediment transfer operating at the catchment scale in the Himalayan-Tibetan orogen, with the view to contributing to the longstanding debate over the role of climate versus tectonics in driving short and long term landscape change. Several approaches have been employed in order to address this question. The first phase of investigation involved the quantification and discussion of the rates and nature of periglacial rockwall slope erosion throughout the NW Himalaya. In *Focus 1* and *2*, slope erosion rates range between 0.02 and 7.2 ± 1.1 mm/a. This magnitude of lateral erosion is argued to be sufficient to influence topographic change at the catchment head across geomorphic timescales (10^5 – 10^2 years), and

emphasizes the importance of localized, periglacial erosion when evaluating broader landscape evolution. Collectively, these studies suggest that the distribution and magnitude of rockwall slope erosion is primarily the result of tectonically driven rock uplift throughout the orogen. Precipitation has a secondary role in influencing rates of slope erosion.

The aim of *Focus 3* and *4* was to further our understanding of the development and abandonment of transient sediment sinks in high altitude, high relief settings, and explore the implications that this has for wider landscape change. These studies suggest that fans and other depositional landforms such as fill terraces evolve during interglacials and periods of deglaciation, which are associated with a higher intensity monsoon. As glacial conditions or periods of relative cooling and increasing aridity become reestablished, these landforms stabilize. Regional incision events in the NW Himalaya are less straightforward as they are recognized across various climatic conditions, likely due to the ubiquitous nature of erosion in these active alpine settings. That said, *Focus 3* and *4* suggest that climate and climate-driven processes largely moderate sediment transfer in the NW Himalaya. A preservation bias in favor of young Holocene records in the monsoon-influenced Himalaya is argued to be the result of rapid background denudation rates. This relationship tentatively extends to the slope and catchment-wide erosion record, where more rapid erosion is focused in regions with shorter records of geomorphic change.

Many studies argue that sediment flux and erosion in Himalayan catchments is primarily a function of orographically focused monsoon rainfall (Bookhagen et al., 2005; Bookhagen and Burbank, 2006; Gabet et al., 2006; Wulf et al., 2010). This dissertation, in part, aligns itself with this argument. *Focus 3* and *4* outline the importance of climate, specifically precipitation in landscape change, yet acknowledge that patterns in precipitation and temperature, and therefore climate driven surface processes, are influenced by the structural evolution of the orogen. *Focus 1* and *2* take this a step further and show that the distribution and magnitude of periglacial slope

erosion is strongly moderated by tectonically driven uplift, yet is unable to discount the influence of precipitation. These opposing conclusions show that neither climate nor tectonics can or should be ignored when investigating processes of erosion and sediment transfer in this mountain setting. It is therefore better to argue that the sedimentary systems of mountain ranges in the NW Himalaya are instead affected by the feedbacks between climate and tectonics, rather than one mechanism in isolation. Crucially these conclusions apply to the regional and/or mountain range scale. On a more local scale, catchments that share similar characteristics and are in close proximity to one another, can record slope and catchment-wide erosion rates that differ by an order of magnitude and/or have asynchronous aggradation and incision events. Each focus of this dissertation therefore concludes that although the patterns of periglacial slope erosion and the development of landforms throughout the NW Himalaya can be explained by a combination of broad scale climate and tectonic processes, the specific nature and rate of geomorphic change in each catchment is likely dictated by longstanding catchment specific feedbacks between topography, geology, surface processes, climate and tectonics. The relative roles of these different parameters and the nature and rates of landscape change are therefore likely to vary across space and time. Studies that discuss similar themes must therefore consider the importance of catchment specific dynamics, while also recognizing that inconclusive or variable records of geomorphic change does not mean that orogen-scale interactions are not at play.

5.2. Cycles of Himalayan catchment sediment transfer

Several theoretical models use sediment availability, sediment transfer or geomorphic event frequency as indexes for landscape change (Ryder 1971; Church and Ryder 1972; Ballantyne et al., 2002b; McColl, 2012). The majority of these models propose that dynamical change is first initiated by the onset of deglaciation, and concludes before the onset of the following glacial. It is unclear whether the stabilization of deglaciated terrain or a 'steady-state' landscape can be

achieved across short interglacial periods in the Himalayan-Tibetan orogen. Catchment-wide landscape change can instead be viewed as a continuum of sediment transfer cycles. This approach has been devised from the findings of this study in combination with the wider geomorphological and glaciological literature of the NW Himalaya.

A set of preconditioning factors (Table 1) and one or more forcing factors trigger a shift in erosion or sediment flux (i.e. step through model; Fig. 2), the effects of which are then carried forward. These cycles can occur in isolation, alongside others, or feed into multiple cycles. For example, a seismic event (i.e. forcing factor, Table 1) triggers the mobilization and transfer of sediment from a rockwall (i.e. source; Fig. 2) to a series of debris cones at the base of the slope (i.e. transient sediment sink; Fig. 2). These debris cones are then part of the revised landscape settings, of which subsequent geomorphic change is conditioned by. Theoretically, this sediment is evacuated from the catchment or mountain range following one or more of these cycles, which can extend across 10^5 – 10^1 years. This approach acknowledges the important contribution of preexisting landscape dynamics and variability in external forcings for landscape development, and offers a useful framework for interpreting the evolution of Himalayan catchments.

6. Future directions

This study has exercised two main approaches to further our understanding of Himalayan landscape change using cosmogenic nuclides: the first to quantify rates of inter-catchment erosion, and the second to constrain the timing and nature of landform development. New research questions and additional research objectives that build upon the progress made in this dissertation have been identified, and are summarized below.

A continued effort to constrain the rates of periglacial rockwall slope erosion in the NW Himalaya would be beneficial. *Focus 1* and *2* highlight concerns over whether one to three medial moraine samples are sufficient to provide ^{10}Be concentrations that are representative of the source area. Sampling systematically up the length of the medial moraine and across different grainsizes would help to address these concerns and assess the variability in nuclide concentrations in the supraglacial realm of glaciers. Moreover, constraining bedrock erosion rates of the rockwalls using cosmogenic nuclides would compliment the detrital erosion record of this dissertation, as well as provide new insights into erosion at the catchment head. Past studies have quantified headwall retreat and slope erosion by dating and estimating volumes of slope deposits such as talus (Andre, 1997; Curry and Morris, 2004; Hincheliff and Ballantyne, 2008) and modeling supraglacial debris flux using remote sensing techniques (Heimsath and McGlynn, 2008; Gibson et al., 2017). Comparing the results of these methods to nuclide derived erosion rates would offer a novel insight into the complexities of landscape change in the periglacial realms of the investigated catchments. Investigating the rock fracturing and other rock properties of the source rockwalls would also help to elucidate some of the controls of the frequency and magnitude of rockfall events in the NW Himalaya.

Secondly, a continued effort to improve the size and resolution of the chronological datasets that define fan development and surface abandonment is a necessary next step. This would involve broadening the variety of investigated fans in terms of type, morphology, size and age. Defining the timing of sedimentary unit deposition for each fan from *Focus 3* using optically stimulated luminescence dating would help to substantiate the timing and drivers of fan aggradation.

This study alongside others, has demonstrated that erosion can vary significantly in both mechanism and magnitude throughout a drainage basin (Wittmann et al., 2009; Scherler et al., 2014; Portenga et al., 2015). These latter studies have used cosmogenic nuclide concentrations in

sediment derived from tributaries, trunk streams and terraces to quantify this variability. A similar project has been developed by the author for the monsoon- influenced Kullu river basin in Himachal Pradesh, with the specific aim of discussing the role of transient sediment sinks in erosion rates inferred using nuclide concentrations. Samples for this project were retrieved in a 2017 field campaign. This project will refer to the Beas Kund slope erosion dataset (*Focus 2*), fan surface ages (*Focus 3*) and regional phases of incision (*Focus 4*) from Kullu to trace sediment transfer throughout a catchment with rapid background denudation rates.

Fig. 1. Overview of the study area in the NW Himalaya. Hillshade map is overlain by total annual precipitation (TRMM 2B31; Bookhagen and Burbank, 2006). Major faults from Hodges (2000) and Schlup et al. (2003). Inset map illustrates the location (black polygon) of the study areas (relief map with swath polygons modified from Bookhagen and Burbank 2006).

Fig. 2. Sediment transfer and erosion processes within a Himalayan alpine catchment showing the sources, sinks (including examples) and mechanisms for sediment transport (blue arrows: fluvial reworking; brown arrows: failures, rockfalls, flows and floods). The nature and rates of each sediment transfer episode involves the geomorphic sequence of landscape modification (Table 1).

Table 1. Geomorphic sequence of landscape modification.

1. PRECONDITIONING		2. FORCING		3. RESULT
Pre-existing geologic settings	Geomorphic regime/history	- Glacial, fluvial, periglacial, hillslope - Regolith characteristics and distribution, stochastic events	Climate	- Moisture (permafrost, frost action/sorting, vegetation change) - Temperature (permafrost, frost action/sorting, vegetation change)
	Lithology	- Rock strength, rock mass quality, jointing and structure	Erosion	- Glacial, fluvial, periglacial, wind
	Tectonic history	- Structural evolution/events, rock uplift	Glaciation	- Glacial processes (destructive and formative)
	Topography	- Slope, relief, hypsometry	Human activity	- Land use change/pressure
		Tectonics	- Rock uplift, seismicity	Adjustment to sediment supply, transfer and storage
		Weathering	- Physical, chemical, biological

ABSTRACT

Rockwall slope erosion is defined for the upper Bhagirathi catchment using cosmogenic ¹⁰Be concentrations in sediment from ablation-dominated medial moraines on Gangotri glacier. Beryllium-10 concentrations range from 1.1 ± 0.2 to $2.7 \pm 0.3 \times 10^4$ at/g SiO₂, yielding rockwall slope erosion rates from 2.1 ± 0.4 to 5.3 ± 1.2 mm/a. Slope erosion rates are likely to have varied over space and time and responded to shifts in climate, geomorphic and/or tectonic regime throughout the late Quaternary. Geomorphic and sedimentological analyses confirm that the moraines are predominately composed of rockfall and avalanche debris mobilized from steep relief rockwall slopes via periglacial weathering processes. Slope erosion affects sediment flux and storage of snow and ice at the catchment head on diurnal to millennial timescales, and more broadly influences catchment configuration and relief, glacier dynamics and microclimates. The slope erosion rates exceed the averaged catchment-wide and exhumation rates of Bhagirathi and the Garhwal region on geomorphic timescales (10^5 – 10^0 years), supporting the view that erosion at the headwaters can outpace the wider catchment. The ¹⁰Be concentrations of medial moraine sediment for the upper Bhagirathi catchment and the catchments of Chhota Shigri in Lahul, northern India and Baltoro glacier in Central Karakoram, Pakistan show a tentative relationship between ¹⁰Be concentration and rainfall. As such there is more rapid slope erosion in the monsoon-influenced Lesser and Greater Himalaya compared to the orogen's semi-arid interior.

We conclude that rockwall slope erosion in the three study areas, and more broadly across the NW Himalaya is likely governed by individual catchment dynamics that vary across space and time.

Keywords: supraglacial processes; sediment flux; glacier; climate; cosmogenic isotopes

INTRODUCTION

Glaciation and glacial erosion are central to the topographic evolution of high altitude mountain belts such as the Himalayan-Tibetan orogen, by influencing rates of sedimentation and localized incision, limiting relief production and elevation, and offsetting tectonic uplift (Brozović et al., 1997; Whipple et al., 1999; Mitchell and Montgomery, 2006; Wulf et al., 2010, 2011; Scherler et al., 2014). The contributions of periglacial erosion at the valley head to the denudation budgets of Himalayan glacierized catchments have been largely overlooked, with the exception of an eloquent study by Heimsath and McGlynn (2008) in the Nepal High Himalaya. This is surprising given that lateral erosion of rockwall slopes via periglacial processes are shown to exceed rates of vertical glacial incision in other alpine settings (Brocklehurst and Whipple, 2006; Foster et al., 2008).

Periglacial weathering processes including freeze-thaw, frost cracking and ice wedging deliver large volumes of rockfall and avalanche debris to the mountain glacier sedimentary system from the valley slopes (Schroder et al., 2000; Matsuoka, 2001; Owen et al., 2003; Hales and Roering, 2005; Sanders et al., 2012; Gibson et al., 2017). The strength of coupling between slope and glacier affect glacier dynamics, catchment sediment flux and can dictate the relief and topographic configuration of catchment divides over time (Thiede et al., 2005; Moore et al., 2009; Montgomery, 2002). Erosion of rockwall slopes in the Himalayan-Tibetan orogen therefore has

broad implications for the distribution of precipitation and the morphological development of its mountain ranges (Burbank et al., 2003; Gabet et al., 2004; Anders et al., 2006; Bookhagen and Burbank, 2006).

The distribution and rates of erosion for the Himalayan-Tibetan orogen scale with tectonics (Burbank et al., 2003; Thiede et al., 2005; Schlerler et al., 2014), topography (Vance et al., 2003) and rainfall (Deeken et al., 2001; Thiede et al., 2004; Grujic et al., 2006; Biswas et al., 2007; Craddock et al., 2007; Gabet et al., 2008; Wulf et al., 2010; Portenga et al., 2015). Erosion at the valley head can outpace catchment and regional landscape denudation rates, and exhibit greater or different sensitivities to local and/or regional external forcing such as shifts in geomorphic, climatic or tectonic regime (Heimsath and McGlynn, 2008; Scherler et al., 2011). We aim to assess the importance of periglacial processes in the Himalayan-Tibetan orogen; an essential first step is the quantification of rockwall slope erosion rates. We chose the upper Bhagirathi catchment of Garhwal, northern India, for this initial investigation. This region is the source area for the Ganges and it contains some of the largest glaciers in the monsoon-influenced Himalaya, including Gangotri glacier. This catchment has a well-defined glacial chronostratigraphy, comprehensive records of past and modern glacier behavior and is easily accessible. We apply geomorphic and sedimentological methods and measure cosmogenic ^{10}Be concentrations in medial moraine sediment to calculate rockwall slope erosion rates. We compare our erosion rates to local catchment-wide erosion and exhumation records to assess the difference between slope erosion and regional landscape denudation in Garhwal. We compare slope erosion rates for upper Bhagirathi, Chhota Shigri in the Lahul Himalaya, northern India and Baltoro in the Central Karakoram of Pakistan with catchment parameters and regional climate records to help identify the factors that may be affecting slope erosion in the NW Himalaya.

REGIONAL SETTING

The Bhagirathi catchment is located in the Uttarkashi district of Uttarakhand, in the Garhwal Himalaya, northern India (Fig. 1). Three major lithotectonic units characterize the geology of the Garhwal Himalaya: 1) Tethyan Himalaya sedimentary series; 2) the High Himalaya crystalline sequence; and 3) the Lesser Himalaya sequence (Searle et al., 1997, 1999; Vannay et al., 2004). Despite the absence of a clear shear zone, Garhwal is bounded in the north by the Tethyan Himalaya low-grade metasedimentary rocks and the South Tibetan Detachment zone (STD; Kumar et al., 2009; Srivastava, 2012). The Main Central Thrust zone defines the southern margin of the region; the boundary between high-grade gneiss, migmatite and granite of the HHS and low-grade metasedimentary rocks of the LHS. The Jhala normal fault trends through central Garhwal and the Bhagirathi catchment, separating quartzo-feldspathic sillimanite gneiss from Harsil metasedimentary rocks (Searle et al., 1999). Maximum regional uplift rates range between 4 and 5.7 mm a⁻¹ (Barnard et al., 2004; Scherler et al., 2014). Neotectonics, which include persistent microseismicity and stochastic earthquakes, greatly influence the geomorphic evolution of the region (Searle et al., 1987; Validya 1991; Rajendran et al., 2000; Barnard et al., 2001; Bali et al., 2003). Detailed summaries of the geologic setting and histories of transient erosion, unroofing and exhumation for Garhwal are provided by Scaillet et al. (1995), Searle et al. (1993, 1999), Sorkhabi et al. (1996) and Scherler et al. (2014; Fig. 1).

The climate of the western Himalaya is influenced by two major climatic systems, the southwest Indian monsoon and the northern hemispheric mid-latitude westerlies (Finkel et al., 2003; Bookhagen et al., 2005; Owen, 2009). The majority of annual precipitation (1000–2500 mm a⁻¹) in Garhwal occurs from July to September; during this time the humid air masses of the Indian monsoon penetrate the high-altitude ranges of the Greater Himalaya (Burbank et al., 2004; Scherler et al., 2010; Thayyen and Gergan, 2010; Wulf et al., 2010). Rainfall magnitudes vary

significantly both seasonally and across short distances (10^1 – 10^2 km) throughout the region, creating localized microclimates that are affected by the variability in terrain and geomorphic regimes (Sharma and Owen, 1996; Barros et al., 2006; Singh et al., 2007; Srivastava, 2012). Most of the annual snowfall above ~1000 m asl occur between December and March (Dobhal et al. 2008; Wulf et al., 2010; Bhambri et al., 2011; Scherler et al., 2014). Glaciers in Garhwal are predominantly fed by winter accumulation, and in turn 97% of river discharge is governed by seasonal snow and glacier melt throughout the region (Singh et al., 2008, Bhambri et al., 2011; Bhattacharya et al., 2016).

Due to the restricted number of meteorological stations located above ~5000 m asl in the Himalaya (Benn et al., 2012; Srivastava, 2012), climate and weather records for the upper Bhagirathi catchment are based on data from only one weather station (Mukhim, 30.6°N, 78.3°E, ~1900 m asl). Mukhim station records mean annual precipitation of 1648 mm and temperature of 15.5°C from 1971 to 2000. An additional weather station has been established at Bhojbasa (~3780 m asl, 30.9°N, 79.0°E), ~4 km from the snout of Gangotri glacier. This station has documented annual temperature ranges between -2.3 and 11°C (2001–09), and a mean winter snowfall of ~546 mm/a (Bhambri et al., 2011).

Montane forests transform to alpine tundra vegetation between ~1000 and 3000 m asl within the upper Bhagirathi catchment. At higher elevations, alpine shrubs and grasses with some sandy-gravel soil development are sparsely distributed or absent (Schweinfurth, 1968; Srivastava, 2012).

The upper Bhagirathi catchment (3400–7200 m asl) covers an area of ~550 km², of which ~50% is glaciated (Tangri et al., 2004; Haritashya et al., 2006; Singh et al., 2006). This transverse catchment is delineated by steep relief peaks (>45°) that exceed 6000 m asl, including Shivling (6543 m asl), Meru (6660 m asl) and the Chaukhamba Massif (7138 m asl; Bhambri et al., 2011;

Satyabala, 2016). Below Gaumukh (~4000 m asl, 30.9 °N, 79.1°E) the catchment is unglaciated and becomes wider and deeper as a result of the calving of a steep gorge by the Bhagirathi River. River terraces are present along the valley floors, most of which are cultivated.

At ~30 km long, Gangotri glacier is the largest glacier in the drainage basin. This temperate glacier is fed by a series of smaller tributary glaciers including Chaturangi and Kirti between elevations of 4005 and 5950 m asl (Dutta et al., 2004; Srivastava, 2012, Haritshya et al., 2010). Gangotri glacier has an estimated volume of ~20–30 km³ (Frey et al., 2014; Bhattacharya et al., 2016), with a thickness ranging from 350 to 450 m in the accumulation zone, and 40 to 65 m at its snout (Srivastava, 2012; Gantayat et al., 2014; Singh et al., 2017). The mean glacier surface velocity is ~48±4.8 m a⁻¹ (Bhattacharya et al., 2016), and the contemporary equilibrium-line altitude (ELA) lies between 4510 and 5160 m asl (Owen and Sharma, 1998; Naithanu et al., 2001; Ahmad and Hasnain, 2004, Burbank et al., 2004; Srivastava, 2012; Singh et al., 2017). Medial moraines of variable thickness are present below the ELA, partially mantling the ~26-km-long ablation zone (Haritashya et al., 2010; Scherler et al., 2011; Satyabala, 2012; Srivastava, 2012). Gangotri glacier has an undulating surface characterized by steep relief ridges and depressions, meltwater channels, drainage ponds and ice collapse features. Large lateral moraines trend parallel to the glacier along the lower ~10 km of the ablation zone, helping to form a series of discontinuous ablation valleys that are in-filled by hillslope and avalanche debris. Lacustrine deposits are present at Tapovan (4330 m asl, 30.9°N, 79.1°E; Sharma and Owen 1996; Ranhotra and Bhattacharya, 2004; Haritashya et al., 2010)

The upper Bhagirathi catchment preserves an abundance of moraines, debris flow/alluvial fans and cones, strath/river terraces and landslides (Owen and Sharma, 1998; Burbank et al., 2004; Singh et al., 2017). Mass movements are particularly prevalent throughout the region as a

consequence of glacial and fluvial erosion, heavy monsoon rains, localized storms and earthquakes, which each enhance slope instability (Owen et al., 1996; Barnard et al., 2001, 2004).

Five glacial stages have been defined within the upper Bhagirathi catchment and include the: Bhagirathi (60–23 ka), Sudarshan (21–16 ka), Shivling (~5.2 ka), Gangotri (~2.4–1.9 ka), Bhujbasa (~1.7–0.5 ka), Meru (~0.3±0.1 ka) and Gaumukh (~0.3–0.2 ka; Sharma and Owen, 1996; Barnard et al., 2004; Puri et al., 2004; Srivastava, 2012; Singh et al., 2017; Saha et al., *submitted*). The low erosion rates measured within the drainage basin (<1 mm a⁻¹; Vance et al., 2003) and wider region (0.15–5.4 mm a⁻¹; Haritashya et al., 2006; Scherler et al., 2014) aid in the preservation of glacial landforms across several glacial cycles. The moraine of the Bhagirathi stage (60–23 ka) is located ~30 km downstream from the present glacier snout and records the oldest and most extensive glaciation of the drainage basin. Gangotri glacier has retreated between 6 and 27 m/a over the past 50 years, but since 2007 has ceased retreat. Tangri (2002), Tangri et al. (2004), Bhambri et al. (2012), Srivastava (2012) and Bhattacharya et al. (2016) provide detailed summaries of the glacier stages and retreat.

METHODOLOGY

Background

Past studies have quantified slope erosion by dating and estimating the volume of slope deposits such as talus (Andre, 1997; Curry and Morris, 2004; Hincheliff and Ballatyne, 2008; Siewert et al., 2012), and modeling supraglacial debris flux (Heimsath and McGlynn, 2008; Gibson et al., 2017). Over recent years slope erosion has been successfully measured using cosmogenic ¹⁰Be concentrations in medial moraine sediment (Heimsath and McGlynn, 2008; Seong et al., 2009; Ward and Anderson, 2011; Scherler and Egholm, 2017). Medial moraines form when rockfall and avalanche debris mobilized from the valley slopes is exhumed to the ablation zone surface after

being buried and transported englacially through the accumulation zone (Matsuoka and Sakai, 1999; Goodsell et al., 2005; MacGregor et al., 2009; Mitchell and Montgomery, 2006; Dunning et al., 2014, 2015). The ^{10}Be concentrations of medial moraine sediment are thought to reflect the mean surface concentrations of the source area (Ward and Anderson, 2011). For a given medial moraine sediment package, the shorter the duration of exposure to cosmic rays on the valley head slope, the lower the accumulation of ^{10}Be , and the faster the inferred slope erosion rate. On sub-millennial timescales the ^{10}Be concentrations are likely to reflect slope erosion via periglacial weathering processes, whereas over geomorphic timescales (10^0 – 10^6 years) the input is more likely affected by local or regional erosion rates (Gibson et al., 2017).

Rockwall slope erosion rates have been measured using ^{10}Be concentrations of medial moraine sediment for the Chhota Shigri catchment of Lahul, northern India (Scherler and Egholm, 2017) and Baltoro glacier catchment in the Central Karakoram, Pakistan (Seong et al., 2009). Slope erosion for Baltoro was shown to be an order of magnitude higher than rates inferred by sediment budgets, and half the fluvial incision and exhumation rates for the region. Seong et al., (2009) hypothesize that the difference between these erosion records indicates differing sensitivities to conditions responsible for erosion. Fluvial incision, for example, is argued to exceed slope erosion because of the influence of local/differential tectonism and/or isostatic uplift.

We combine this method with geomorphic and sedimentological analyses of Gangotri glacier medial moraines to constrain rates of rockwall slope erosion for the upper Bhagirathi catchment.

Field Methods

Detailed geomorphic maps of the upper Bhagirathi catchment were constructed in the field with the aid of Landsat ETM+ data (acquired in 2003), topographic maps generated from a 3-arc second (~30 m) STRM DEM and Google Earth imagery. Geomorphic and sedimentological

techniques described by Benn and Owen (2002) were applied to identify and differentiate between landforms and sediment deposits.

Six major medial moraines were identified on the surface of Gangotri glacier (Fig. 2). Each moraine was named, the initial term *SD* for the supraglacial debris moraine and a subscript letter from *A-F*. The moraine sourced from the Kirti tributary valley is referred to as *SD_A*, for example. The *SD_{A-C}* moraines are the focus of this study as they are the largest and most accessible moraines on the glacier, and extend throughout the ablation zone, making them most likely to reflect bedrock slope erosion rates of the upper Bhagirathi catchment. The traditional moraine nomenclature, e.g., *M_{1-x}*, was not used to avoid confusion with Gangotri terminal and lateral moraines.

Sediment samples from each moraine were collected where possible at intervals from the snout to ~3 km up-glacier. The moraines were inaccessible beyond this point due to major instabilities in both hillslopes and glacier surface. The samples were taken from high relief, stable and well-defined moraine ridges, to avoid input from external sources including lateral moraines and hillslope deposits. The sampling locations were ≥ 20 m² in area to avoid sampling from a single rockfall event. Detailed sedimentological and geomorphic descriptions of the moraine were taken at each location. Approximately 3 kg of sediment was collected for each sample, with a grain size range of <3 cm (clay-coarse gravels) applying bulk sediment sampling methods of Gale and Hoare (1991).

Two samples were collected from the *SD_A* moraine, three from *SD_B* and one from *SD_C*. The samples were numbered in ascending order for each moraine, from the furthest up-glacier to the closest to the snout of Gangotri glacier. *G_{sup1}* sample (subscript sup1), e.g., was collected at 4315

m asl, ~3 km from the terminus. The location of each sample was recorded using a handheld Garmin Etrex 30 GPS unit and then photographed.

Medial moraine sediment analysis

Particle size distribution was determined by dry sieving each sample into five size fractions using the Wentworth (1922) particle size classification, following the techniques of Allen (1981). These fractions include: coarse-medium gravel (8–32 mm), fine gravel (2–8 mm), coarse-medium sand (0.25–2 mm), fine sand (63–250 μm) and silt and clays (<63 μm).

Particle shape analysis of sediment with a grain size of <1 mm and a consistent lithology, typically involves the examination of 100 grains per sample or 50 grains per size fraction (Hambrey and Glasser, 2003; Owen et al., 2008; Hambrey et al., 2008; Lukas et al., 2013). Given the larger grain size range (0–3 cm) and variability in lithology, we analyzed 100 grains per size fraction, totaling 500 per sample, to facilitate the comparison with other records. The size fractions of each sample were prepared using dilute HCl acid (0.1%, >12 hours) and a deionized water rinse. The fine sands, and silts and clays were examined using a digital microscope and scanning electron microscope (SEM) respectively, in the Sedimentology Laboratories and Advanced Material Characterization Center (AMCC) at the University of Cincinnati.

Clast roundness for each size fraction was determined using the Powers (1953) visual estimation chart and modified criteria of Ballantyne and Benn (1994). Clast sphericity for each size fraction was determined using the visualization charts of Zingg (1935). The clast shape of each sample was derived using the Snead and Folk (1958) criteria; the three orthogonal axes (a, b and c axes) of 100 grains per size fraction were plotted using a Graham and Midgley (2000) ternary diagram.

We use the Benn and Ballantyne (1994) covariance plot methods to determine the origins and transport histories of the medial moraine sediment. This method plots the C_{40} indices (c:a axes ratio <0.4) and roundness index (RA and RWR, the percentage of very angular-angular and well rounded-rounded clasts respectively) of unclassified sediment alongside control samples of supraglacial, extraglacial (e.g. hillslope deposits), moraine, subglacial, meltout and fluvial sediment samples. Our samples are compared with control samples from high altitude alpine settings detailed in Lukas et al. (2012, 2013), in the absence of viable control samples for the Himalayan-Tibetan orogen. We recognize that there is great variability within glacial sedimentary environments and are therefore cautious when interpreting these plots.

The percentage of clast surface weathering was determined for 100 quartz sand grains (0.25–2 mm) for each sample using the visual estimation charts of Sheridan and Marshall (1987) and Owen et al. (2003). Each clast was assigned to a weathering class (<10 , 10–20, 20–40, 40–60, 60–80 and 80–100%), and a mean surface weathering was calculated for each sample.

Approximately 10 g of the silt-clay fraction of each sample was treated with sodium pyrophosphate (0.02 N) and then centrifuged to disperse the clay component from the remainder of the sub-sample. The clay fraction of each sample was mounted onto three glass slides using the smear mount method outlined by Moore and Reynolds (1997) for air-dried, ethylene glycol solvation and oven dried (450°C) slide analysis. Each set of three sides was analyzed using the X-ray Diffractometer in the X-ray Laboratory at the University of Cincinnati. The clay mineralogy of each sample was identified using the databases of Chenn (1977) and Moore and Reynolds (1997). The percentage component for each clay mineral was calculated using methods of Underwood and Pickering (1996) and Mac.Diff. 4.2.5 software.

Be-10 production rates and geochemical analysis

Beryllium-10 production rates for the upper Bhagirathi catchment were calculated using methods outlined by Dortch et al. (2011). The production rates were calculated from a STRM DEM with a spatial resolution of 30 m, using a revised sea-level high-latitude spallogenic production rate of 4.08 ± 0.23 Be atoms $\text{g}^{-1} \text{a}^{-1}$ (Martin et al., 2017; <http://calibration.ice-d.org/>) and a ^{10}Be half-life of 1.36 Ma (Nishiizumi et al., 2007) in MATLAB R2017.a. The production rate for each pixel was corrected for topographic shielding and then averaged to derive the mean ^{10}Be production rate for the catchment.

The sieved fractions were once more combined, crushed and re-sieved to attain the 250–500 μm fraction. This process helps to avoid bias in the contribution of any one grain size to the geochemical analysis of the sample. Quartz isolation, dissolution, chromatography, isolation of Be and the preparation of BeO were undertaken in the Geochronology Laboratories at the University of Cincinnati using the community standards and chemical procedures described by Kohl and Nishiizumi (1992), Nishiizumi et al. (1994), and Dortch et al. (2009). After mounting into steel cathodes, the $^{10}\text{Be}/^9\text{Be}$ of each sample were measured using accelerator mass spectrometry at the Purdue Rare Isotope Measurement (PRIME) Laboratory at Purdue University (Sharma et al., 2000).

Portenga et al. (2015) have demonstrated that when native ^9Be is factored into $^{10}\text{Be}/^9\text{Be}$ ratios, irrespective of geologic setting, the resultant ^{10}Be concentrations and inferred erosion rates can be significantly altered (20-400 %). The native ^9Be measured in ~ 5 g fractions of clean quartz per Gangotri sample was negligible (< 1 ppm), so no adjustment to the $^{10}\text{Be}/^9\text{Be}$ ratios was made. A procedural blank $^{10}\text{Be}/^9\text{Be}$ ratio correction of $3 \pm 1 \times 10^{-15}$ was made for each sample. Muogenic production is negligible for the timescales of processes characterized for this study (Brown et al., 1995; Braucher et al., 2003). Corrections for quartz content variability between samples was

considered unnecessary in this setting (Ahmad et al., 2001; Vance et al., 2003). Minimum rockwall slope erosion rates were calculated using the ^{10}Be concentrations and catchment-wide production rates by applying methods described in detail by Lal (1991), Granger et al. (1996), Balco et al. (2008) and Dortch et al. (2011).

Ward and Anderson (2011) suggested that ^{10}Be accumulation within moraine debris during supraglacial transport down-glacier is negligible in landscapes with denudation rates of ≤ 1 mm/a. Accordingly, no corrections to ^{10}Be concentrations for Gangotri glacier were necessary. As some catchment erosion rates in Garhwal exceed this threshold (0.13–5.37 mm/a; Vance et al., 2003; Lupker et al., 2013; Scherler et al., 2014), ^{10}Be accumulation during this phase of glacier surface transport was calculated using methods of Seong et al. (2009; Supplementary Item 1). The revised rates significantly exceed the original rates (>18.7 – 3.4 mm/a) and are not considered to reflect the rockwall slope erosion rates of the catchment accurately, and are therefore not referred to herein.

Medial moraines in the Himalayan-Tibetan orogen including Bhagirathi are primarily composed of rockfall debris; smaller rockfall events occurring frequently across time and space, interjected by larger and less frequent events (Dunning et al., 2014; Rowan et al., 2015). Despite much of the volumetric erosion being achieved by these larger events, this bias within the sediment source in favor of small rockfall events means that the resultant erosion rates should be considered minimum estimates. Unique sediment exchange processes in the supraglacial environment (Scherler et al., 2009; Ward and Anderson, 2011; Lukas et al., 2012, 2013; Lupker et al., 2012; Scherler et al., 2015), sediment storage and remobilization, shifting geomorphic regimes and ice/snow shielding (Bierman and Steig, 1996; Scherler et al., 2014; Fame et al., 2018) are also likely to affect the ^{10}Be concentrations, and mean that the derived erosion rates reflect minimum rates. Interpreting the ^{10}Be concentrations of sediments in medial moraines is made more

challenging because of the variability in production rates for alpine catchments and lack of uniformity in the ^{10}Be inventories at the bedrock surface, which vary over temporal and spatial scales. A detailed summary of this methodology and its assumptions are provided by Ward and Anderson (2011).

Topographic and geomorphic analyses

ASTER DEMs and Landsat ETM+ data were used in conjunction with GIS Spatial Analyst tools for additional topographic analyses including catchment slope, 3-km-radius relief, hypsometry and aspect. These parameters are defined for the glacial-periglacial realms of the upper Bhagirathi catchment only, as this is the area that pertains to the focus of our study. Topographic analyses of Chhota Shigri catchment in Lahul, northern India and Baltoro catchment in the Central Karakoram, Pakistan was also conducted to enable comparisons between slope erosion and catchment characteristics across the NW Himalaya.

Upper Bhagirathi catchment temperature reconstructions

The altitudinal-temperature gradient or adiabatic lapse rate ($\Delta T/\Delta Z$) for high relief mountain settings typically range between 6 and 11°C/km (Derbyshire et al., 1991; De Scally, 1997; Thayyen et al., 2005; Siddiqui and Maruthi, 2007; Bashir and Rasul, 2010; Pratap et al., 2013; Kattel et al., 2013, 2015). Conventional wisdom is that regional lapse rates better account for temporal and spatial variations, although their application within alpine settings such as the Himalayan-Tibetan orogen is particularly challenging due to the lack of weather stations (Blandford et al., 2008). We use an adiabatic environmental lapse rate of 7°C/km asl, a product of both an approximate median for the orogen, and a lapse rate derived from the local weather stations of Mukhim (~1900 masl) and Bhojbasa (~3780 masl). This lapse rate is used to estimate the summer and winter surface temperatures throughout the upper Bhagirathi catchment.

The optimum frost cracking envelope defined by Hales and Roering (2005) falls between mean annual temperatures of -8 and -3 °C. Bhagirathi catchment elevations which have surface temperatures within this range were determined using the chosen lapse rate and a 30-m-resolution SRTM DEM. The frost-cracking envelope was also calculated with respect to depth by modeling the thermal structure of the near surface of the catchment using methods outlined in detail by Anderson and Anderson (2010). A thermal diffusivity of 1.15 mm²/s was used as it reflects an approximate midpoint in diffusivity values for the following substrates that characterize the catchment; regolith, landforms and deposits, and bedrock. This provides an estimate for the rate of heat transfer from the surface. The spatial distribution and depth of permafrost (0 °C; Brown, 1970) was also calculated for the catchment using the same methods as described above. Despite offering a reasonable assessment of the frost cracking and permafrost distribution, these simplified methodologies involve a series of assumptions about the physics, temperature data and geologic setting (Anderson and Anderson, 2010). Caution must therefore be exercised when interpreting this data, particularly because surface temperatures of Bhagirathi will have varied over space and time. These analyses aim to determine whether slope failure in the upper Bhagirathi catchment can be influenced by surface temperature and the associated periglacial weathering processes.

ELA and snowline altitude (SA) reconstructions

ELAs and ELA depressions (Δ ELA) were calculated for the contemporary and past glacial stages within the upper Bhagirathi catchment using methods described by Osmaston (2005), Benn et al. (2005), Heyman (2014) and Sharma et al. (2016). To reduce the uncertainties inherent within these reconstructions, a mean ELA was calculated for each glacial stage from reconstructions derived from each of the following methods: area-altitude (AA); area accumulation ratio (AAR) with ratios of 0.4, 0.5 and 0.6; and toe-headwall accumulation ratio (THAR) with ratios of 0.4 and 0.5; Benn et al. 2005). This approach has been successfully applied in Ladakh, northern India

(Dortch et al., 2010; Orr et al., 2017, 2018; Saha et al., 2018) and the Karakoram (Seong et al., 2007), reflecting accurate estimates of the ELAs. Our study adopts methods strongly recommended by Porter (2001), whereby the mean ELA of a glacial stage also provides an estimation of the snowline altitude. The aim of these analyses is to evaluate the effect of the timing and nature of glaciation on the rates of bedrock slope erosion throughout the last glacial.

Medial moraine descriptions

Gangotri glacier system has six major medial moraines on its surface; the three investigated moraines of this study (SD_{A-C}) extend over 50% of the length of the glacier's ablation zone (Fig. 2; Table.1). The medial moraines are composed of supraglacial diamict, and like many alpine glaciers, the debris thickness is heterogeneous over space and time (10^1-10^4 years), ranging from a few millimeters to several meters thick (Owen, 1989; Schroder et al., 2000; Benn et al., 2012; Srivastava, 2012). This heterogeneity contributes to variations in the surface morphology, mass balance and flow velocities of the glacier (Benn and Owen, 2002; Rowan et al., 2005; Swift et al., 2005; Haritashya et al., 2006; Hambrey et al., 2008; Gibson et al., 2017), in addition to affecting the glacier's sensitivity to climatic and environmental change (Scherler et al., 2011a,b).

The moraine morphologies are characterized by irregular surface topographies, the result of variable diamict thicknesses, and distribution and orientation of steep relief ridges, depressions and ice cliffs. The widths of the moraines range from 50 to 650 m, widening towards the snout of Gangotri glacier (Fig. 2; Supplementary Item 2).

These supraglacial diamicts are composed of massive sandy boulder gravels with a finer sandy-silt matrix containing interstitial ice (Fig. 3; Supplementary Item 3). The subangular-very angular boulder gravels have surfaces that range from unweathered to moderately weathered. Striations or

chattermarks are not present on any clast size. Large boulders (>2–0.25 m) are located on or slightly offset from the moraine ridges with some evidence of varnish and previous toppling.

Finer sediment increases with proximity to the debris-ice interface, likely as a result of sorting through rainfall and meltwater flows (Hasnain and Thayyen, 1996). These fine sediments, and evidence of frost action on pebbles–boulders, indicate active periglacial weathering processes and continued sediment production and/or clast modification by interclast attrition and abrasion across the glacier surface (Owen et al., 2003; Benn and Evans, 2010; Benn et al., 2012). No clear englacial sediment horizons were identified in the field, despite some evidence of englacial silts and sands at the glacier surface. The exhumation of subglacial sediment to the englacial or supraglacial system is therefore likely to be very localized (Owen et al., 2003). Discontinuous soil development and tundra vegetation are restricted to the stable medial moraine ridges.

The diamicts are composed of biotite granite, tourmaline leucogranite, with some gneiss, mica schist and quartzite, reflecting the local bedrock (Searle et al., 1999; Srivastava, 2012). Sediment samples are composed of granites and schists, with the exception of the SD_A samples that include some gneiss clasts.

SD_A moraine

The SD_A medial moraine extends ~12 km from the Kirti tributary catchment to within ~500 m of the snout of Gangotri glacier (Fig. 2). A medial moraine from a Kirti sub-catchment coalesces with the main tributary moraine at 4670 m asl. SD_A narrows in width at the confluence (~600–300 m) between Kirti tributary and Gangotri glaciers, as a result ice deformation and shearing (Hubbard et al., 2004; Gibson et al., 2017).

The SD_A diamict has a unique rusty brown color, likely the result of the weathering of the local Augen gneiss or Vaikrita group gneiss bedrock slopes (Fig. 3B). Sharing the same source outcrops, the medial moraine (SD_E) of Ganohim glacier also has this coloration.

G_{sup1} (30.9°N, 79.09°E, 4315 m asl) was retrieved ~3 km from the glacier snout. G_{sup2} (30.9°N 79.08°E) was collected at 4280 m asl, ~500 m downstream and northwest of G_{sup1} .

SD_B moraine

SD_B is the centermost, gray medial moraine of Gangotri glacier that extends ~15 km from the modern ELA (4510–5160 m asl) to the glacier snout (Fig. 3B, 4). SD_B is the most stable moraine of this study, with proportionally fewer ice cliffs, ice collapse features and interstitial ice within the diamict matrix.

G_{sup3} (30.89°N, 79.09°E) was retrieved at 4325 m asl, ~300 m northeast of G_{sup1} , ~3 km from the glacier terminus. G_{sup4} (30.90°N, 79.09°E) was collected ~500 m northwest and down glacier from G_{sup3} , at 4285 m asl. G_{sup5} (30.92°N, 79.08°E) was sampled ~500 m from the glacier snout at 4130 m asl.

SD_C moraine

SD_C also extends ~15 km from the modern ELA to the glacier snout. The diamict has a slightly darker gray coloration to the SD_B moraine (Fig. 3D).

Due to access, only one sample could be retrieved from this moraine, ~500 m from the glacier snout. G_{sup6} (30.92°N, 79.08°E) was collected at 4130 m asl, slightly upstream from the confluence between the Raktavaran tributary catchment and Gangotri trunk glacier.

RESULTS

Medial moraine sediment analysis

Gangotri glacier medial moraine samples consist of medium-coarse sands and fine gravels; these fractions together account for 71–73% by weight of each sample. There are variations in the particle-size distributions between the moraines and between samples taken from specific moraines (Fig. 5; Supplementary Item 4). Caution must be exercised when interpreting shifts in particle size distribution with distance down-glacier, as only three or fewer samples are collected from each moraine.

Sediments from the SD_A moraine become progressively coarser down-glacier, the percentage component of fine gravels increasing from 30 to 55% between G_{sup1} and G_{sup2} , and the fraction of medium-coarse sands decreasing from 36 to 26% (Fig. 5). Depletion in the finer sediment fractions is also observed; sediment with particle sizes <0.25 mm (fine sand–clay) decrease from 28 to 11%. The supraglacial sediment of SD_A is marginally coarser than the other moraines of this study.

The particle size distribution of the SD_B moraine sediment fluctuates with distance down-glacier, other than a slight increase in the fine and medium-coarse gravel fractions. The percentage component of medium-coarse sands for this moraine range between 37 and 63%, and is the highest of this study.

The SD_C moraine has the largest percentage component of medium-coarse gravels of this study, at 14%.

No significant relationship can be identified between particle size distribution and proximity to the glacier snout when assessing down-glacier sediment transport as a whole. Whilst the percentage of medium-coarse gravels and silts-clays increase and decrease down-glacier respectively, the remaining fractions (fine sands–fine gravels) have fluctuating percentage distributions. The greatest proportion of fine sediment (silt-clay; $<75 \mu\text{m}$) for the SD_A and SD_B moraines are found in the samples located furthest from the glacier snout ($G_{\text{sup}1}$, $G_{\text{sup}3}$). This fine sediment fraction is likely either mobilized down-glacier by meltwater processes and rainfall or introduced by another source.

Comparisons between these records are restricted to sediment fractions $<4 \text{ mm}$, due to the particle size range of available datasets. The percentage component of each particle size broadly decreases with particle size for medial moraine samples from Gangotri glacier and existing studies from the European Alps, Iceland and Norway (Fig. 6). There is some deviation from this trend for the SD_A and SD_B moraines, where the sediment is predominantly composed of medium-coarse sands. The percentage silt content of these moraines is either similar or higher than supraglacial sediment recovered from other glacial systems. Gangotri glacier medial moraine sediment is therefore largely finer than the supraglacial sediment from previous studies, based upon this particle size range alone.

Gangotri glacier medial moraine samples are largely made up of angular (32–48%) and subangular (19–46%) grains, with $\leq 1\%$ of grains considered either rounded or well rounded (Fig. 7). Accordingly, grains of low sphericity constitute between 71 and 82% of each sample. No significant relationship can be identified between grain size and particle roundness or sphericity for any one moraine or sediment sample (Supplementary Item 5, 6).

The bladed (14–23%) and very bladed (30–40%) particle shape classes are the most prevalent for Gangotri glacier samples, where over 50% of grains per sample have c:a and b:a ratios <0.3 (Supplementary Item 7). Compact grains constitute <10% of each sample. The SD_A moraine sees a minor increase in the bladed and very bladed components of its samples with distance down-glacier, whilst SD_B sees a slight increase in the bladed and decrease in the very bladed fractions. The SD_C moraine records the highest percentage values of very bladed and very platy grains of this study, 40 and 28% respectively.

The covariance of clast shape and roundness indices are presented in RA- C_{40} and RWR- C_{40} plots for Gangotri glacier and previous studies in Fig. 8. Distinguishing between transport pathways must be approached with care due to the pronounced overlap in facies indices. The RA (85–94%) and C_{40} (75–96%) indices and large proportion of bladed and extremely bladed grains suggest that the medial moraines of this study share a supraglacial transport history (Benn and Owen 2002; Hubbard 2004; Lukas et al., 2013). Some extraglacial and moraine control samples also record RA values greater than 80%. The RWR indices for the medial moraines range between 6 and 15%, higher than the ~0% values typical for supraglacial samples. The more rounded component of the samples may reflect the input of sediment from other realms of the glacial system, or clast rounding by englacial and/or supraglacial transport, or the effects of meltwater on the glacier surface. The SD_C moraine's proximity to Raktavaran and Chaturangi tributary glaciers may result in the receipt of sediment from its subglacial, proglacial and fluvial system and therefore may explain the high RWR value (15%) of G_{sup6} .

Percentage surface weathering estimates of quartz grains for Gangotri glacier range from 30 to 100%, with mean surface weathering ranging from 66 ± 22 to $78\pm 17\%$ (Fig. 9). A slight, yet negligible increase in surface weathering can be identified down glacier for the SD_A and SD_B moraines, and the glacier as a whole. A bimodal frequency distribution of surface weathering

(peaks at ~50% and 80–90%) transforms to a unimodal distribution (peak at 80%) with greater proximity to the glacier snout (Supplementary Item 8, 9).

The clay component of the SD_A G_{sup1} and G_{sup2} samples are made up of a mixed layer illite/smectite (97.1 and 97.7% of total sample, respectively) and a chlorite fraction (Supplementary Item. 10). The percentage smectite for the mixed layer group is 56% for G_{sup1} and 55% for G_{sup4} , and is likely to be the product of the preferential weathering of volcanic source rocks, namely the Augen or Vaikrita group gneiss. The illite and chlorite component of this moraine sediment is typical of a glacial setting and reflects the low-grade metamorphism of the Bhagirathi region (Birkeland 1974; Chamley 1989; Regmi et al., 2013). This mixed layer illite/smectite is also present in SD_B 's G_{sup3} (25% smectite), making up 95.4% of the sample's clay fraction, the outstanding component being chlorite. The clay component of the remaining SD_B G_{sup3} and G_{sup5} samples is largely made up of illite, with 1.5 and 0.8% chlorite, respectively. Similarly, the G_{sup6} clay fraction from the SD_C moraine is composed of 98.2% illite and 1.8% chlorite.

Rockwall slope erosion rates of the upper Bhagirathi catchment

G_{sup1} and G_{sup2} from the SD_A moraine have ^{10}Be concentrations of 1.1 ± 0.2 and $1.6\pm 0.3 \times 10^4$ at/g SiO_2 , respectively. These concentrations infer bedrock slope erosion rates of 5.3 ± 1.2 mm/a for the G_{sup1} sample, and 3.6 ± 1.2 mm/a for G_{sup2} (Table. 2). The G_{sup3} , G_{sup4} , and G_{sup5} samples from the SD_B moraine have ^{10}Be concentrations of 2.7 ± 0.3 , 2.5 ± 0.3 and $2.6\pm 0.3 \times 10^4$ at/g SiO_2 respectively. An inferred erosion rate of 2.1 ± 0.4 mm/a is derived from G_{sup3} , 2.3 ± 0.4 mm/a from G_{sup4} , and 2.2 ± 0.4 mm/a from G_{sup5} . The SD_C G_{sup6} sample has a ^{10}Be concentration of $1.5\pm 0.4 \times 10^4$ at/g SiO_2 and an inferred erosion rate of 3.8 ± 1.1 mm/a.

Geomorphic analyses

The detailed geomorphic mapping of upper Bhagirathi (Fig. 2) reveals that the identification of discrete geomorphic zones within the catchment is not possible owing to the absence of the vertical stratification of landforms (Fig. 2; Supplementary Item 11). Terraces and fans occupy elevations <5000 m asl, whereas the remaining landforms extend the full extent of the upper Bhagirathi catchment.

The slopes of the upper Bhagirathi catchment range from 0 to 75°, gentle (<30°), moderate (31–45°) and steep (>46°) slopes occupying 38, 25 and 37% of the total catchment, respectively. The mean tributary catchment slopes of the study area range between 30 and 41° (Table. 1). Between 10 and 53% of the catchment areas are occupied by glaciers; the glacier surface slopes are included within this catchment slope analysis, which introduces a degree of uncertainty to these mean slope values. Catchment 3-km-radius relief ranges from 1.4±0.4 to 2.2±0.3 km.

Steep relief slopes that exceed 35° are largely unable to support regolith, snow or ice (Gruber and Haerberli, 2007; Nagai et al., 2013). Srivastava (2012) maintains that ~50% of the catchment's bedrock slopes have angles >60°. The steep topography of the catchment therefore means that it is susceptible to both rockfall and avalanching (Hewitt, 1988; Bookhagen et al., 2005; Dunning et al., 2007; Gruber and Haerberli 2007; Mitchell et al., 2007), which likely provides the primary source of supraglacial sediment on Gangotri glacier (Srivastava, 2012).

Ideal conditions for periglacial weathering processes including frost-shattering, cryofracturing, and frost heave are present throughout the upper Bhagirathi catchment. Optimum frost cracking conditions (-3–-8°C) within the catchment migrate from elevations of ~5680–6380 m asl during the summer, to ~3780–4480 m asl during the winter. This is consistent with the frost-cracking envelope between 4000–6000 m asl devised by Brozović et al. (1997) for the NW Himalaya.

These temperatures extend to a maximum depth of ~2.3 m into the near-surface between 3780 and 4430 m asl (Fig. 10).

Peaks which exceed ~6380 m asl (including Shivling, Meru and the Chaukhamba Massif) have surface temperatures which are lower than -8°C , which theoretically reduces the efficiency of periglacial weathering processes. The distribution and magnitude of these processes are affected by diurnal and seasonal cycles and climatic and microclimatic variations. With the gradual warming of temperatures over the last few glacial cycles, optimum frost cracking conditions are likely to have extended to lower elevations within the catchment than the present.

Transient or seasonal permafrost can occur at elevations between 3380 and 5280 m asl within the catchment; at higher elevations the permafrost can be permanent. Transient permafrost, which exacerbates slope instabilities and mass wasting (Fischer et al., 2006), may extend from the catchment slopes to the proglacial zone of Gangotri glacier and valley floor. Permafrost penetrates the near surface between 3080 and 3380 m asl, to a maximum depth of 0.8 m (Fig. 10).

ELA and SA reconstructions

The ELAs of contemporary glaciers in the Bhagirathi catchment range from 4880 to 5665 m asl (Table. 3), falling within the uncertainties of, and marginally above past estimates of 4510–5390 m asl (Owen and Sharma, 1998; Naithanu et al., 2001; Ahmad and Hasnain, 2004, Burbank et al., 2004; Srivastava, 2012; Singh et al., 2017).

Gangotri glacier has retreated ~30 km upstream over the past ~60 ka (Owen and Sharma, 1998; Burbank et al., 2004), the ELA rising from 4095 ± 295 to 5160 ± 160 m asl, giving an ΔELA of 1065 ± 320 m. Over this timescale this is an impressive retreat of glacier ice; glacial studies across the Transhimalaya of northern India (Dortch et al., 2011; Orr et al., 2017, 2018) and the Tibetan

plateau (Heyman et al., 2014) document maximum Δ ELAs between 240–290 and 280–494 m, respectively. This rate of recession has yet to be identified in Garhwal, where local glacial stages record Δ ELAs <100 m within the past 1 ka, compared to an Δ ELA of 465 ± 140 m for Gangotri glacier. A net loss in glacier volume since 1.6 ka is indicated by the heights of the ice-contact Gangotri glacial stage moraines relative to the glacier surface. Approximately 50% of the total catchment is above the modern snowline altitude (5160 ± 160 m asl).

DISCUSSION

Bhagirathi rockwall slope erosion

Medial moraine sediment characteristics for the lower ~ 3 km of the ablation zone of Gangotri glacier are broadly similar, despite the discrete origins of each landform. Particle shape analysis indicates a predominantly supraglacial transport history with possible contributions from other landscape realms, i.e. moraine, extraglacial. Clast roundness and surface weathering is attributed to periglacial weathering processes including freeze thaw, frost cracking and ice wedging, which dislodge angular rock fragments from the bedrock slopes and/or regolith (Benn and Lehmkuhl, 2000; Schroder et al., 2000; Benn et al., 2003; Hambrey et al., 2008; Lukas et al., 2012). Moisture availability, surface temperatures (Hales and Roering, 2007; Humphreys and Wilkinson, 2007; Moores et al., 2008; Dühnforth et al., 2010; Fischer et al., 2010, 2012; West et al., 2014; Eppes and Keanini, 2017) and rock mass strength (Augustinus, 1995; Wegmann et al., 1998; Murton et al., 2006; Eppes and McFadden, 2008) moderate the hillslope debris flux. The steep relief topography of the Bhagirathi catchment promotes hillslope-glacier coupling through mass wasting events including rockfalls and avalanching (Brozović et al., 1997; Anderson, 2005; Matsuoka and Murton, 2008; Foster et al., 2010; Scherler et al., 2011b). Rockfalls play a significant, if not principal role in the rockwall slope erosion, which is consistent with the observation that mass movements are the dominant mechanism for Himalayan landscape

denudation (Gabet et al., 2004; Dortch et al., 2009; Lupker et al., 2012). The frequency and magnitude of rockfall events over 10^5 – 10^3 year timescales are likely controlled by regional erosion rates, which are moderated by climate and/or tectonism (Molnar et al., 2007; Scherler et al., 2014; Gibson et al., 2017). The larger fine-sediment component to the samples from Gangotri glacier compared with other alpine glaciers (Fig. 6) may be explained by: 1) enhanced physical weathering of clasts; 2) input of fines from external sources; or 3) the preferential sampling of smaller grain sizes. Significant chemical weathering of moraine sediment is unlikely within these alpine environments, particularly in the absence of carbonate rocks (France-Lanord et al., 2003; Garzanti et al., 2007; Tripathy and Singh, 2010).

The ^{10}Be concentrations vary between the samples of each Gangotri glacier moraine and between individual landforms, despite sharing similar sediment characteristics (Fig. 11). No relationship is evident between ^{10}Be concentration and distance down-glacier. The range in ^{10}Be concentrations of our dataset ($1.1 \pm 0.2 \times 10^4$ – $2.7 \pm 0.3 \times 10^4$ at/g SiO_2) may be due to insufficient sediment mixing, the prior or punctuated exposure to cosmic rays, shielding by snow, ice or regolith, or weathering (Seong et al., 2009; Ward and Anderson, 2011; Heyman et al., 2011).

The SD_A moraine records the lowest ^{10}Be concentrations, corresponding to the highest interpreted erosion rates of this study. The close proximity of SD_A to rockwall slopes and external sediment sources along the length of the landform, and the possible greater sensitivity of smaller catchments to external forcing, are two possible explanations for these lower nuclide concentrations. The concentration disparity between the SD_A samples may be due to the sampling of isolated rockfall event(s) rather than amalgamated moraine sediment.

Similarly, the sedimentology and low ^{10}Be concentrations of SD_C 's G_{sup6} may be the result of sediment input from proximal rockwall slopes at the snout of Gangotri glacier or contributions from Raktavaran and/or Chaturangi tributary glaciers.

The SD_B samples have the highest ^{10}Be concentrations of this study ($2.5\pm 0.3\times 10^4$ – $2.7\pm 0.3\times 10^4$ at/g SiO_2), which each fall within uncertainty of each other, and record the lowest interpreted slope erosion rates (2.1 ± 0.4 – 2.3 ± 0.4 mm/a). The SD_B moraine extends the full length of the ablation zone of Gangotri glacier with no direct contact to the catchment slopes. Accordingly, the SD_B rates are considered to be the most representative of upper Bhagirathi catchment rockwall slope erosion. To test the robustness of our interpretations, it would be worthwhile to extend this investigation up-glacier and evaluate variations in ^{10}Be concentrations throughout the ablation zone, and across grain sizes.

The ELA reconstructions for the glacial stages show that the spatial extent of the glacier and periglacial realms has decreased significantly over the past 60 ka, which means that the slope area contributing debris directly to the glacier surface has reduced. Studies suggest that the timing and nature of glaciation and the associated geomorphic landscape change for the upper Bhagirathi catchment is governed by climate. The magnitude and rates of rockwall slope erosion are therefore not only intrinsically linked to climate through periglacial weathering processes, but also as a result of climate-driven glaciation affecting the extent of slope-glacier coupling. Accordingly, rates of rockwall slope erosion and the contribution of the periglacial realms to the denudation budget of the catchment is likely to have fluctuated throughout the last glacial.

Garhwal landscape denudation

Scherler et al. (2015) have shown that rates of fluvial incision in Garhwal during the late Pleistocene was greater than the present by a factor of ~ 2 – 4 . Whether periglacial erosion has

remained constant across these timescales or followed the patterns of fluvial incision, the influence of rockwall slope erosion on the topographic evolution of upper Bhagirathi is likely have been maintained over time. Hillslope erosion in this alpine setting is likely to affect the sediment flux and storage of snow and ice from diurnal to millennial timescales, and then more broadly influence catchment configuration, microclimates (Bhambri et al., 2011; Srivastava, 2012), limit relief and affect the architectural organization of the local fault systems (Validya, 1991; Sorkhabi et al., 1996; Bali et al., 2003). The frequency and magnitude of rockfall events in Bhagirathi may have been affected, in part, by catchment-specific conditions, and external shifts in climate, geomorphic or tectonic regime. The global intensification of late Pleistocene glaciation, for example, caused extensive mass redistribution and localized incision throughout the Himalayan-Tibetan orogen (Zeitler et al., 2001; Brozović et al., 1997; Bookhagen et al., 2005; Hewitt, 2009; Whipple, 2009). This is likely to be similar in the Bhagirathi catchment where landscape denudation could be attributed to the changing glacier mass balance over time.

The rates of rockwall slope erosion largely exceed the averaged catchment-wide and exhumation rates of Bhagirathi and the Garhwal region (Fig. 11). Comparing these rates is challenging as they reflect landscape change through a variety of mechanisms and across different temporal and spatial scales. However, our erosion dataset supports the view that erosion of alpine headwaters outpace the wider drainage basin (Oskin and Burbank, 2005; Naylor and Gabet, 2007), and that the distribution and magnitude of erosion can vary significantly over short distances downstream (Scherler et al., 2014). The higher rockwall slope rates of 2.1 ± 0.4 – 5.3 ± 1.2 mm/a in the Bhagirathi catchment compared with the catchment-wide rates of 0.1 ± 0.001 – 5.4 ± 0.5 mm/a suggest that catchment headwaters are more sensitive to external forcing than the wider catchment. Alternatively, the difference in denudation rates may be because our dataset offers a higher resolution record of erosion than those on the catchment or mountain range scale, or that these latter records eliminate the ‘noise’ in sediment flux data over time, such as single mass

wasting events initiated by large and/or stochastic seismic events (Sadler and Jerolmack, 2014; Willenbring et al., 2013). The slope erosion rates of this study remain lower than the regional uplift rates of 4–5.7 mm/a (Barnard et al., 2004; Scherler et al., 2014), which may explain the preservation of high relief slopes within the study area.

Rockwall slope erosion of the NW Himalaya

Comparisons of ^{10}Be concentrations in medial moraine sediment of Gangotri glacier with similar datasets from Chhota Shigri in Lahul (Scherler and Egholm, 2017) and Baltoro glacier in the Central Karakoram (Seong et al., 2009) show that the ^{10}Be concentrations at these other localities exceed those in our study (Fig. 12). The SD_B samples that are considered to best reflect Bhagirathi slope erosion measure ^{10}Be concentrations $>1 \times 10^4$ at/g SiO_2 lower than Chhota Shigri or Baltoro, and record erosion rates twice as fast. The ^{10}Be concentrations of the three study areas are compared with catchment parameters and regional climate records to decipher the possible drivers of rockwall slope erosion in the NW Himalaya (Fig. 12).

No significant relationship is evident between catchment area and ^{10}Be concentrations (Fig. 12). The catchment area does not account for the total surface area of the source bedrock slopes, a parameter that may influence these concentrations to a greater extent. Approximately 80, 50 and 53% of the total catchment area of Bhagirathi, Chhota Shigri and Baltoro respectively, are above the ELA/SA altitudes and nourish the glaciers through snow and ice avalanching. Changes to the snowline altitude over time likely affect the relative abundance of exposed bedrock and regolith-covered slopes and therefore dictate the hillslope debris flux. Similarly there is no correlation between ^{10}Be and glacier area, and by association, size of medial moraine.

No relationship is apparent between mean slope and ^{10}Be concentration, despite other studies being able to link these variables on a catchment scale and show that greater slope angles promote

a larger debris flux (Finlayson et al., 2002; Burbank et al., 2003; Ouimet et al., 2009; Scherler et al., 2011b, 2014). Although the slopes will broadly facilitate rockfall and avalanching (Luckman, 1977; Gruber and Haerberli, 2007; Bernhardt and Schulz, 2010; Nagai et al., 2013) and the eventual evacuation of sediment from the catchment, each of the study areas is also able to store extensive volumes of sediment in the form of landforms and sediment deposits (Fig. 2; Seong et al., 2009). These landforms typically have gentler slopes, which transfer sediment to the glacier surface via diffusive creep processes (Carson and Kirkby, 1972). Not only will these stores of sediment have implications for the sediment flux of the catchments, but also they may influence the ^{10}Be concentrations measured within medial moraine sediment.

The 3-km-radius relief of the study areas exceed ~ 1.6 km, the steeper relief catchments measuring the highest ^{10}Be concentrations, and therefore the lowest interpreted bedrock slope erosion rates. This suggests that rates of bedrock slope erosion can in some cases be insufficient to limit catchment relief in the NW Himalaya. A more likely explanation is that the 3-km-radius relief is largely dictated by the local uplift of the study areas.

The temperature data is recovered from weather stations outlying the study areas and therefore does not accurately reflect catchment temperatures. The ranges in annual recorded temperatures prevent any correlations being made between this climatic parameter and ^{10}Be . The high altitude setting of each study area with mean catchment elevations >4000 m asl (Fig. 12D) does however mean that the rockwall slopes of each catchment lie within the Brozović et al. (1997) 4000–6000 m asl frost cracking window for the NW Himalaya.

A tentative relationship lies between total annual rainfall and ^{10}Be concentrations, where higher rainfall coincides with higher interpreted rockwall slope erosion rates. This supports the extensive work on the coupling between precipitation and erosion in the Himalaya, where enhanced

moisture in the monsoon-influenced Lesser and Greater Himalaya is thought to drive more rapid landscape denudation, compared to the semi-arid interior of the orogen (Benn and Owen 1998, 2002; Harper and Humphrey, 2003; Bookhagen et al., 2005; Anders et al., 2006; Bookhagen and Burbank, 2006; Gabet et al., 2008; Owen, 2009). This relationship is not completely straightforward for our study areas however, as ^{10}Be concentrations shared by samples from Baltoro glacier ($4.4\pm 0.3 \times 10^4$ – $11.7\pm 2.2 \times 10^4$ at/g SiO_2) and Chhota Shigri (3 – 6×10^4 at/g SiO_2) experience contrasting annual rainfall of <500 and >900 mm, respectively. The complex climate-topography interactions of each study area prevent a conclusive relationship between erosion and this climatic parameter from being identified. This association does suggest however that rockwall slope erosion is sensitive to precipitation and therefore the glacial-periglacial realms of Himalayan catchments are likely to respond to major climatic events and/or environmental change over time.

Studies across the Himalayan-Tibetan orogen have drawn tentative links between erosion and climo-topography (Scherler et al., 2011a,b, 2014; Bookhagen et al., 2005; Bookhagen and Burbank, 2006; Gruber and Haeberli, 2007; Dortch et al., 2011). Our regional assessment of the NW Himalaya has demonstrated that no single discussed parameter provides a dominant control for bedrock slope erosion. We must therefore consider what other variables may be influencing landscape change in these high altitude settings.

Although glacial erosion is considered secondary to periglacial processes; glacier dynamics may affect the rates of rockwall slope erosion. Temperate glaciers, which occupy the monsoon-influenced Himalaya, erode the glacier bed through quarrying and abrasion, which can exploit fractures at the base of the glacier valley slopes (Benn and Evans, 2014; Benn and Owen, 2003). Glacier retreat and changes to mass balance can also lead to the debuttreasing of these slopes. These processes can affect the hillslope debris flux and either contribute to, or trigger mass

wasting (Church and Slaymaker, 1989; Watanabe et al., 1998; Ballantyne, 2002a,b). In the semi-arid Himalaya, sub-polar glaciers frozen to the bed are unlikely to further slope denudation processes and therefore would maintain low erosion rates. Glacial velocity, hydrology and snow blow may also affect the rates of slope erosion over time (Matsuoka and Sakai, 1999, Mitchell and Montgomery, 2006; MacGregor et al., 2009; Scherler et al., 2011b; Barr and Spagnolo, 2015).

The large range of ^{10}Be concentrations and the relatively uniform rock mass strength across the study areas suggest the absence of a dominant lithological control to the rates of rockwall slope erosion. Investigating the jointing, structure and moisture content of the catchment walls would help to evaluate the ongoing damage of frost action and the susceptibility of the rock to failure (Hallet et al., 1999; Murton et al., 2006; Hales and Roering, 2007).

Studies throughout Garhwal and the NW Himalaya have underpinned a tectonic control within the distribution and magnitude of erosion, where erosion is strongly influenced by the Indo-Asian convergence and rock uplift patterns dictated by the geometry and shortening of the Main Himalayan Thrust (Burbank et al., 2003; Thiede et al., 2005; Scherler et al., 2014). Although contributing to this work is beyond the scope of this study, persistent seismicity throughout the Punjab, Himachal Pradesh and Uttarkhand districts of northern India may introduce a neotectonic control to landscape evolution (Bali et al., 2003; Scherler et al., 2014). In Garhwal for example, the 1991 Uttarkashi (M 6.1; Valdiya, 1991; Owen et al., 1996; Bali et al., 2003) and 1999 Chamoli (M 6.6; Rajendran et al., 2000) earthquakes occurred during the applicable timescales of the Bhagirathi erosion record and may have therefore triggered mass redistribution on a sufficient scale to affect the erosion rates of our study.

The mobilization and transfer of sediment from the valley walls to the glacier surface is an example of one of the primary stages in the evacuation of sediment from a glacierized catchment. Models of sediment transfer on the catchment scale argue that a shift in sediment flux requires a set of preconditioning factors and one or more forcing factor (Ballantyne, 2002a,b; McColl, 2012). This is true of the upper Bhagirathi catchment, where the preexisting landscape dynamics, which include catchment parameters, and transitions in climate, tectonic or geomorphic regime, are necessary to explain the nature and rates of bedrock slope erosion over time. Understanding the topographic evolution and configuration of Bhagirathi and glacierized catchments throughout the NW Himalaya is made particularly challenging as it involves processes that operate across a variety of temporal and spatial scales. Despite the controls of the evolution of alpine headwaters remaining elusive, this is the first study to quantify the rates of bedrock slope erosion in the upper Bhagirathi catchment, which has helped to demonstrate the importance of rockfall processes within mountain sedimentary systems.

CONCLUSION

Rockwall slope erosion has been defined for the upper Bhagirathi catchment by three medial moraines of Gangotri glacier. Bedrock slope erosion of the catchment is best reflected by the SD_B moraine interpreted rates, which range from 2.1 ± 0.4 to 2.3 ± 0.4 mm/a. Rockwall slope erosion would have likely varied over space and time, and responded to shifts in climate, geomorphic and/or tectonic regime throughout the late Quaternary.

The rockwall slope erosion rates exceed the averaged catchment-wide (0.1 ± 0.001 – 5.4 ± 0.5 mm/a) and erosional exhumation (1.5 ± 0.5 mm/a) rates of Bhagirathi and the Garhwal region, indicating that erosion at the headwaters can outpace downstream reaches and the wider catchment. A possible explanation is that the high altitude periglacial settings of upper Bhagirathi have a

greater sensitivity to external forcing such a shift in climatic conditions, than the wider catchment or mountain range. Alternatively, the variance found between the rates of landscape denudation may be due to the difference in the temporal and spatial resolution of the erosion records.

Rockwall slope erosion rates are higher in upper Bhagirathi compared to the catchments of Chhota Shigri in the Lahul Himalaya and the Baltoro glacier in the Central Karakoram. Comparisons were made between the erosion datasets of these three study areas and catchment parameters and regional climate records, including catchment and glacier area, mean elevation and slope, 3-km-radius relief and annual temperature and rainfall. A tentative relationship is evident between erosion and rainfall, where more rapid slope erosion was recorded in the monsoon-influenced Lesser and Greater Himalaya, compared with the semi-arid interior of the orogen. No other individual catchment attribute was found to offer a control on the rates of slope erosion in the NW Himalaya.

We were unable to confidently link rockwall slope erosion with climo-topography. We conclude that bedrock slope erosion in the three study areas and then more broadly across the NW Himalaya is likely governed by individual catchment dynamics, which vary across space and time. The frequency and magnitude of rockfall and avalanche events is therefore determined by a set of preconditioning factors unique to each catchment, and one or more local and/or regional forcing factor.

By continuing to decipher the rates and controls of rockwall slope erosion, we will improve our understanding of the role and importance of periglacial processes in the morphological development of mountain ranges and contribute to future studies of sediment flux and wider landscape change across the orogen.

Fig. 12. Comparisons between ^{10}Be concentrations of the Bhagirathi, Chhota Shigri (1: Scherler and Egholm, 2017) and Baltoro (2: Seong et al., 2009) glaciers (uncertainties expressed to 1σ). A) ^{10}Be concentrations. Inset indicates the 1σ uncertainties of the Bhagirathi samples, B) Catchment area (r^2 value provided for all catchment data), C) Glacier area, D) Mean catchment elevation, E) Mean slope (slope calculated from 0.001km^2 catchment grid cells), F) 3-km-radius relief, G) Annual mean temperature for Bhagirathi (Bhambri et al., 2011), Chhota Shigri (Wagnon et al., 2007) and Baltoro (Mihalcea et al. 2006, 2008), H) Annual rainfall for Bhagirathi (Bhambri et al., 2011, Srivastava, 2012), Chhota Shigri and Baltoro (TRMM rainfall record [1998–2005]; Bookhagen and Burbank, 2006).

Table 1. Catchment and glacier characteristics of the upper Bhagirathi catchment (uncertainties are expressed to 1σ)

Catchment	Catchment characteristics					Glacier characteristics			
	Area (~km ²)	Relative relief ¹ (km)	Max. slope ² (°)	Mean slope ² (°)	HI Index ³	¹⁰ Be production rate (at/g/a)	Glacier area (~km ²)	Glacier head (m asl)	Glacier aspect (°)
Gangotri (trunk)	772.7	1.7±0.4	72	36.5±15.2	0.4	95.4±12.2	409.0	6000	330
Raktavaran	139.0	1.6±0.3	68	37.1±15.1	0.5	104.4±13.5	39.3	6280	260
Chaturangi	214.8	1.7±0.3	60	33.9±13.9	0.4	95.4±11.9	124.1	6125	270
Swachhand	39.3	1.7±0.3	57	31.2±13.8	0.4	102.8±13.3	15.1	5820	220
Maiandi	19.5	1.7±0.3	75	40.7±18.4	0.3	107.3±13.9	17.3	6000	200
Sumeru	12.3	1.4±0.4	57	29.6±15.7	0.4	90.6±11.7	12.2	5450	60
Ganohim	35.1	2.2±0.3	61	35.4±19.0	0.3	96.0±12.4	24.2	5735	45
Kirti	79.5	2.1±0.2	63	35.1±14.7	0.3	93.1±12.1	25.2	6300	45
Meru	23.6	2.0±0.3	61	37.5±18.3	0.4	87.0±11.3	8	5540	30

1: 3-km-radius relative relief

2: Slope calculated from 0.001 km² catchment grid cells

3: Strahler (1952) Hypsometric Index (mean elevation- min elevation/relief)

Table 2. Gangotri glacier medial moraine sample AMS ratios, ^{10}Be concentrations and interpreted erosion rates.

Sample	Medial moraine	AMS $^{10}\text{Be}/^9\text{Be}$ ratio ¹ (10^{-14})	^{10}Be concentration (10^4 at/g)	Applicable time range ² (a)	Erosion rate ³ (mm/a)
G _{sup1}	<i>SD_A</i>	1.1±0.2	1.1±0.2	112.4	5.3±1.2
G _{sup2}	<i>SD_A</i>	1.6±0.3	1.6±0.3	165.1	3.6±0.8
G _{sup3}	<i>SD_B</i>	2.7±0.3	2.7±0.3	280.9	2.1±0.4
G _{sup4}	<i>SD_B</i>	2.0±0.2	2.5±0.3	262.9	2.3±0.4
G _{sup5}	<i>SD_B</i>	2.3±0.3	2.6±0.3	272.6	2.2±0.4
G _{sup6}	<i>SD_C</i>	1.7±0.5	1.5±0.4	159.9	3.8±1.1

1: Ratios are corrected for background ^{10}Be detected in procedural blank ($0.3\pm 0.1 \times 10^{-14}$)

2: Applicable time range follows Lal (1991).

3: Erosion rate calculated with mean ^{10}Be production rate for upper Bhagirathi catchment (95.4 ± 12.2 at/g/a), ^{10}Be decay constant of $5.1\pm 0.3 \times 10^{-7}$, and a ^{10}Be half-life of 1.36 Ma.

Table 3. Reconstructed ELAs for the upper Bhagirathi basin (uncertainty is expressed as 1σ)¹

	Time (ka)	Area-Altitude AA	Area-Accumulation ratio			Toe-Headwall altitude ratio		Mean ELA (m asl)	Δ ELA (m asl)
			AAR(0.4)	AAR(0.5)	AAR(0.6)	THAR(0.4)	THAR(0.5)

ABSTRACT

Steep north-south trending gradients in elevation, relief, rock uplift and precipitation make the NW Himalaya an excellent location to examine the relative roles of climate and tectonics in erosion and landscape evolution. We define the distribution and magnitude of periglacial rockwall slope erosion across 12 catchments in northern India using cosmogenic ¹⁰Be concentrations in sediment from medial moraines. Beryllium-10 concentrations range from $5.3 \pm 0.8 \times 10^4$ to $260.0 \pm 12.5 \times 10^4$ at/g SiO₂, which yield erosion rates between 0.02 and 7.2 ± 1.1 mm/a. Between ~0.02 and ~7 m of lateral erosion can therefore be achieved in this setting across a single millennia, and >2 km when extrapolated for the whole Quaternary. This erosion is therefore sufficient to affect catchment sediment flux and glacier dynamics, and help to set the pace of topographic change at the headwaters of catchments. We combine rockwall erosion records from Garhwal, Kullu, Lahul, Ladakh and Baltistan to create a regional erosion dataset. Rockwall slope erosion largely outpaces the local catchment-wide erosion rates and exhumation in the NW Himalaya. This demonstrates the importance of accounting for localized erosion (<10¹ km²) and its effects on down-catchment reaches in studies of wider landscape change. The erosion of rockwall slopes is likely dictated by longstanding feedbacks between topography, geology, surface processes, climate and tectonics, which are specific to each catchment. The relative role of these parameters is likely to vary across space and time.

*Corresponding author. E. N. Orr: orreh@mail.uc.edu

Rockwall slope erosion rates become progressively less rapid with distance north from the Main Central Thrust and into the interior of the orogen. The distribution and magnitude of this erosion is most closely associated with records of Himalayan denudation and rock uplift. This suggests that tectonically driven uplift, rather than climate, provide a first order control on patterns of landscape change in the NW Himalaya, on geomorphic (10^2 – 10^5 years) to geologic (10^6 years) timescales. Precipitation is likely to play a secondary role in defining the spatial distribution of erosion.

Keywords: rock uplift; climate; periglacial erosion; cosmogenic isotopes; sediment flux

INTRODUCTION

A growing number of studies have underlined the importance of periglacial rockwall slope erosion in high altitude mountain settings, and its role in catchment sediment flux, relief production, topographic configuration and glacier dynamics (Heimsath and McGlynn, 2008; MacGregor et al., 2009; Seong et al., 2009; Ward and Anderson, 2011; Benn et al., 2012; Scherler and Egholm, 2017; Orr et al., *in review*). The lateral erosion of slopes has been shown to exceed rates of vertical incision through glacial and fluvial processes, and therefore to a greater extent than previously thought, contribute to denudation budgets and landscape change on the catchment and mountain range scale (Brocklehurst and Whipple, 2006; Foster et al., 2008).

Short and long-term erosion in the Himalayan-Tibetan orogen is understood to scale with tectonics (Burbank et al., 2003; Scherler et al., 2014; Godard et al., 2014), rainfall (Thiede et al., 2004; Grujic et al., 2006; Clift et al., 2008; Gabet et al., 2008; Wulf et al., 2010; Deeken et al., 2011) and/or topography (Vance et al., 2003; Scherler et al., 2011, 2014). Which of these parameters, if any, provide a first-order control on rates of rockwall slope erosion is unclear. The

Himalaya is an excellent location to evaluate these controls, given the south-north gradients in elevation, relief, rock uplift and precipitation (Bookhagen and Burbank, 2006, 2010; Scherler et al., 2011).

Orr et al. (*in review*) were the first to discuss the distribution of rockwall slope erosion throughout the NW Himalaya, and identified a tentative relationship between slope erosion and precipitation. Higher rates of erosion, e.g., were determined for catchments with enhanced monsoon precipitation. Rather than identifying a single control, their study instead suggests that rockwall slope erosion is more complex, and is therefore determined by the interaction between geology, tectonics, climate and topography, which are specific to each catchment. This opposes the view that in tectonically active mountain ranges, the strength of hillslope-glacier coupling is largely controlled by rock uplift and topographic steepness (Scherler et al., 2011; Gibson et al., 2017).

In this study, we seek to better define the distribution and magnitude of rockwall slope erosion in the NW Himalaya, by building upon the work of Orr et al. (*in review*) and quantifying erosion rates for a suite of 12 catchments. Rates of rockwall slope erosion are derived from ^{10}Be cosmogenic nuclide concentrations measured in sediment from medial moraines. Our new erosion dataset is combined with existing slope erosion records from Seong et al. (2009), Scherler and Egholm (2017) and Orr et al., (*in review*). This regional rockwall erosion dataset is compared to records of catchment-wide erosion and exhumation for the NW Himalaya to evaluate the extent to which slope erosion may differ to other records of landscape change, which have been averaged across various spatial and temporal scales. We compare patterns of slope erosion to those in geology, tectonics, climate and topography to resolve the primary controls of rockwall slope erosion in the NW Himalaya. Finally, we determine to what extent slope erosion and its controls, in this high-altitude and high relief setting, can contribute to the longstanding debate over the significance of climate versus tectonics in driving both short and long term landscape change.

REGIONAL SETTING

The Himalayan-Tibetan orogen has formed as the result of the continued continental collision and partial subduction between the Indian and Eurasian lithospheric plates (Searle et al., 1997). The Indus-Tsangpo Suture Zone defines the collision zone between these plates in the NW Himalaya and contains remnants of the Neo-Tethys Ocean, which include ophiolite mélanges. The suture zone marks the northern boundary of the Tethyan Himalaya; a unit of weakly metamorphosed Proterozoic–Paleogene sedimentary rocks including pelite and psammite (Searle, 1986; Steck et al., 1998; Schlup et al., 2003). Between the early Miocene and Pleistocene, deformation driven crustal shortening initiated the development of a sequence of foreland propagating thrust systems that divide the lithotectonic units that lie south of the Tethyan Himalaya. The South-Tibetan Detachment and the Main Central Thrust bound the Greater Himalaya Crystalline Core Zone to the north and south, respectively. This sequence is composed of Precambrian–Paleozoic high-grade metamorphic amphibolite-grade schist, gneiss and migmatites, which are intruded by Cambrian–Ordovician, Permian and Miocene granitic plutons (Frank et al., 1973; Searle and Fryer, 1986; Walker et al., 1999; Miller et al., 2001; Vannay et al., 2004). This unit has been divided into two sub-units: southern Greater Himalaya sequence (GHS-S) and northern Greater Himalaya sequence (GHS-N; DeCelles et al., 2001; Thiede and Ehlers 2013). South of the Main Central Thrust, the Lesser Himalaya sequence consists of medium-high grade mica schist and granitic gneiss, and low-grade Proterozoic metasedimentary rocks, which include phyllite, quartzite and limestone (Upreti, 1999; Miller et al., 2000; Vannay et al., 2004). The Sub-Himalaya is composed of detrital sediment eroded from the Himalayan arc between the Oligocene and Pliocene, and is bounded to the north and south by the Main Boundary Thrust and Main Frontal Thrust, respectively (Vannay et al., 2004).

Continued crustal shortening and thrust and strike-slip faulting throughout the orogen means that the NW Himalaya remains tectonically active (Hodges et al., 2004; Vannay et al., 2004; Bojar et al., 2005), even though some regions in northern India such as Ladakh, have undergone tectonic quiescence or dormancy since the early Miocene (Kristein et al., 2006, 2009). Hodges (2000), Yin and Harrison (2000) and Streule et al. (2009) provide further details of the Himalayan lithotectonic units and the timing of movement throughout the fault systems.

Two atmospheric systems primarily govern northwest Himalayan climate; the Indian summer monsoon that advects moisture from the Indian Ocean between late May and September, and the Northern Hemispheric westerlies, which bring moisture from the Mediterranean, Black and Caspian seas between December and March (Gadgil 2003; Lang and Barros 2004; Wulf et al., 2010; Mölg et al., 2013). A steep south-north precipitation gradient became established during the late Miocene, perpendicular to the strike of the mountain belt (~8 Ma; Qiang et al., 2001; Liu and Dong, 2013), due to the high elevation ranges of the Greater Himalaya inhibiting the northward migration of moisture to the interior of the orogen. Monsoon air masses are forced to ascend, condensate and form clouds along the Himalayan front, which creates a rainshadow down the leeward side of this orographic barrier (Bookhagen et al., 2005a,b; Wulf et al., 2010). During times of increased monsoon strength, moisture is thought to penetrate farther into the interior of the orogen (Finkel et al., 2003; Bookhagen et al., 2005a,b; Wulf et al., 2010). The northern hemispheric westerlies operate at higher tropospheric levels to the Indian summer monsoon. The orographic capture of moisture transported by this atmospheric system is therefore focused in high elevation ranges (> 4500 m asl) as winter snowfall (Weiers 1995; Lang and Barros 2004). Today, total annual precipitation declines from ~1500–3000 mm in the Lesser and Greater Himalaya ranges, to <150 mm in the interior of the Tethyan Himalaya and Tibetan Plateau (Bookhagen and Burbank, 2006).

The distribution and magnitude of precipitation has been shown to vary both temporally and spatially throughout the Himalayan-Tibetan orogen during the late Quaternary (Burbank et al., 2003; Bookhagen et al., 2005a,b). Fluctuations in monsoon strength driven by changes in orbital insolation, the migration of the intertropical convergence zone, convective localized monsoon storms and sporadic heavy rainfall are thought to cause some of this variability (Finkel et al., 2003; Owen et al., 2008; Thomas et al., 2016). On the local-regional scale (10^{2-4} km²), topography and wind direction exert controls on the migration of moisture throughout the NW Himalaya (Bookhagen et al., 2005a,b), and create localized microclimates throughout individual mountain ranges (Benn and Owen, 1998; Bookhagen and Burbank, 2010; Wulf et al., 2010). Landscape change in the NW Himalaya is precipitation sensitive, where shifts in the availability and source of moisture has been shown to initiate changes to sediment flux, hillslope processes (Bookhagen et al., 2005; Bookhagen and Burbank, 2006; Sharma et al., 2017; Kumar et al., 2018; Orr et al. *in press*) and the timing of glaciation (Owen and Dortch, 2014; Saha et al., 2018).

The timing and forcing of glaciation can also vary across short distances (10^{1-2} km) in the NW Himalaya (Owen and Dortch 2014). Studies have shown that the nature of glaciation can be influenced by climatic factors such as shifts in the strength or behavior of regional and/or global atmospheric and oceanic systems (Owen and Sharma 1998; Watanabe et al., 1998; Solomina et al., 2015; 2016; Saha et al., 2018) and/or local geological factors such as topography and glacier type (Barr and Lovell 2014; Anderson et al., 2014). The Himalayan Holocene stages (HHs; Saha et al., 2018), semi-arid western Himalayan-Tibetan orogen stages (SWHTs; Dortch et al., 2013) and monsoonal Himalayan-Tibetan stages (MOHITs; Murari et al., 2014) provide regional syntheses of the glacial records throughout the NW Himalaya (Table 1).

Study areas

In this study, the Ladakh region refers to the Ladakh and Zaskar Ranges of Jammu and Kashmir in northern India. The Baltistan region encompasses the semi-arid Karakoram of Pakistan (Fig. 1). The Indian summer monsoon delivers two-thirds of the annual precipitation in the Ladakh and Zaskar Ranges (total: 87 mm/a; Table 1), whereas the westerlies provide the primary source of moisture to the Karakoram. Glaciers in the Ladakh region are small (1–10 km²) cold-based sub-polar glaciers, which are precipitation sensitive and sublimation dominated (Benn and Owen, 2002).

Geomorphic studies recognize that the arid/semi-arid climatic setting of the Ladakh region is largely responsible for the preservation of very old landforms and sediment deposits (>400 ka; Owen et al., 2006; Hedrick et al., 2011; Orr et al., 2017, 2018, *in press*) and slow rates of landscape change (<0.07±0.01 mm/a; Dortch et al., 2011a; Dietsch et al., 2015, *in revisions*). Dortch et al. (2011) argue that the higher rates of catchment-wide erosion observed throughout the northern flanks of the Ladakh range (0.06±0.01–0.07±0.01 mm/a), compared to south-facing catchments (0.02±0.003–0.04±0.008 mm/a) is due to tectonic uplift along the active Karakoram fault and the tectonic tilting of the central range. This study suggests that catchment-wide erosion is unable to keep pace with regional uplift; erosion rates are at least an order of magnitude slower than the rates of uplift inferred by strath terrace incision (0.02±0.003–2.6±1.9 mm/a; Kristein et al., 2006, 2009; Dortch et al., 2011b; *ibid*). Bedrock incision rates of ~0.6 mm/a by rivers in some north-facing catchments over the past ~120 ka are equal to local rates of exhumation (0.4–0.6 mm/a). Dietsch et al. (2015) use cosmogenic nuclide concentrations in bedrock tors to demonstrate that periglacial weathering at catchment ridgelines in the Ladakh Range is greater in glaciated catchments than those that have remained unglaciated. Bedrock erosion rates in the periglacial domain of these catchments are higher than downstream reaches; interfluvial bedrock

ridges yield erosion rates ($<7.0 \pm 1.0 \times 10^4$ mm/a) an order of magnitude slower than the bedrock tors ($50.0 \pm 5.0 \times 10^4$ – $100.0 \pm 10 \times 10^4$ mm/a).

The investigated Gopal and Stok catchments are two north-facing transverse catchments in the high-altitude desert landscapes of the northern Zaskar Range in Ladakh, and each retain small valley glaciers (Fig. 1, 2; Table 1). Karzok and Mentok are northeast-trending catchments that drain the Rupshu Massif in central Zaskar of the Ladakh region. Cirque glaciers occupy the upper reaches of these catchments.

The Lahul region includes the Lahul-Spiti and Kullu districts of the Pir Panjal and Greater Himalaya ranges in the Himachal Pradesh of northern India. The majority of annual precipitation in this region is sourced from the Indian summer monsoon (950–1020 mm/a; Table 1), despite a large area of Lahul being in the rainshadow of the Himalayan front. Glaciers are large, temperate and melt dominated, and are fed by precipitation from the summer monsoon and westerlies (Benn and Owen, 2002; Su and Shi, 2002). Differential rates of fluvial incision during the Holocene range from 0.2 ± 0.2 to 13.2 ± 6.3 mm/a along the length of the Chandra valley in Lahul, and either equal, or exceed regional rates of tectonic uplift (Adams et al., 2009; Dortch et al., 2011a). These rates of fluvial incision are argued to reflect the variable valley response to past glaciation and the complex and active tectonic setting in Lahul. The Plio-Pleistocene Apatite Helium cooling ages for the GHS-S rocks in Lahul measure exhumation rates of ~ 1 – 2 mm/a from 2.5 Ma (Sorkhabi et al., 1999; Vannay et al., 2004; Adams et al., 2009).

The Urgos valley glacier extends throughout the upper reaches of a southeast trending tributary catchment of the Miyar basin in the Lahul-Spiti district (Fig. 2). Panchi is a north-facing catchment with a small valley glacier, located north of the Keylong and Darcha villages. Shitidar, Batal, Chhota Shigri and Hamtah are north facing tributary catchments with one–two valley

glaciers. Each catchment drains into the Chandra valley. Beas Kund is a southeast trending catchment located on the southern slopes of the Pir Panjal Range in the Kullu district. Two valley glaciers occupy this catchment.

The Indian summer monsoon also dominates annual precipitation in the Uttarkashi district of Uttarkhand in the Garhwal Himalaya, northern India, a region our study revisits. Catchment-wide erosion rates range from ~0.1 to 0.5 mm/a in the Lesser Himalaya and from ~1 to 2 mm/a in the Greater Himalaya (Vance et al., 2003; Scherler et al., 2014). Scherler et al. (2014) argue that the spatial variability in catchment erosion is primarily controlled by topographic steepness. This study and others conclude that the distribution of erosion is influenced by patterns of rock uplift (4–5.7 mm/a) which are dictated by the geometry and shortening of the Main Himalayan Thrust (Burbank et al., 2003; Barnard et al., 2004; Schlerer et al. 2014).

METHODOLOGY

A suite of 12 accessible catchments was selected for investigation along the south-north precipitation gradient of the NW Himalaya (Fig. 1, 2). Each catchment supports either a cirque or small valley glacier with distinct and well-preserved medial moraines. Geomorphic maps of the periglacial-glacial realms of these catchments were prepared in the field and then refined using Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) global digital elevation models (GDEMs; 30-m-resolution), Landsat Enhanced Thematic Mapper Plus (ETM+) imagery and Google Earth imagery. Topographic and geomorphic matrices including catchment area, 3-km-radius relief, mean slope, hypsometry and aspect were calculated using the Spatial Analyst Toolbox in ArcMap 10.1. These analyses were also conducted for the Baltoro catchment in the Central Karakoram of Pakistan (Seong et al., 2009) and the upper Bhagirathi catchment in

Garhwal, northern India (Orr et al., *in review*) to enable comparisons between rockwall slope erosion and catchment matrices throughout the NW Himalaya.

We define rates of rockwall slope erosion by measuring ^{10}Be concentrations in medial moraine sediment. Rockwall slope erosion is inversely proportional to the ^{10}Be concentrations measured in these landforms (Seong et al., 2009; Ward and Anderson 2011). The longer the rockwall slopes are exposed to cosmic rays before the debris is transferred to the glacier surface by rockfall processes, the greater the ^{10}Be concentration in the sediment and therefore the slower the inferred rockwall slope erosion rate. Details of this methodology and its assumptions are provided by Ward and Anderson (2011) and Orr et al. (*in review*).

Orr et al. (*in review*) argue that the rates of rockwall slope erosion in the upper Bhagirathi catchment are best represented by the erosion rates derived from the centermost SD_B medial moraine of Gangotri glacier. This is because the ^{10}Be concentrations of SD_B fall within uncertainty of each other, and that as the most stable of the three investigated moraines, it did not receive sediment input from lateral moraines or hillslopes along the ablation zone of the glacier. The study also suggests that multiple samples should be taken from each medial moraine and/or glacier to evaluate variability in slope erosion throughout the catchment. With these recommendations in mind, we collected between one and five samples from stable and well-defined medial moraine ridges for the 12 investigated catchments (Fig. 2, 3). The sample locations were $\geq 20 \text{ m}^2$ in area to avoid sampling from a single source slope or rockfall event. Approximately 3 kg of sediment with a grain size of $<3 \text{ cm}$ (clay-coarse gravels) were collected for each sample by applying bulk sediment sampling methods of Gale and Hoare (1991). Each sample was named using the initial term 'G' for 'glacier' and then an abbreviated term for the catchment name. The samples were numbered in ascending order from the glacier snout, for

glaciers with more than one sample. For example, the G_{Ch1} sample was located closest to the snout of Chhota Shigri in Lahul, whilst G_{Ch5} was located furthest up-glacier.

The extraction of quartz from the sediment samples and ^{10}Be sample preparation was conducted at the Geochronology Laboratories at the University of Cincinnati, applying the community standards and chemical procedures of Kohl and Nishiizumi (1992). The $^{10}\text{Be}/^9\text{Be}$ of the samples was measured using accelerator mass spectrometry at the Purdue Rare Isotope Measurement (PRIME) Laboratory at Purdue University (Sharma et al., 2000). Upon the recommendations of Portenga et al. (2015), native ^9Be measured in $\sim 5\text{g}$ fractions of clean quartz from each sample was subtracted from the initial ratio. Ward and Anderson (2011) designed an analytical expression to quantify the accumulation of cosmogenic nuclides during the transport of sediment from the source slopes to the medial moraine. This study found that ^{10}Be accumulation during the burial, englacial transport and exhumation of sediment to the glacier surface was negligible in landscapes with denudation rates $\leq 1\text{ mm/a}$. This model was implemented in our study because some of the records of erosion local to our investigated catchments, particularly in Garhwal, exceed this threshold (0.13–5.37 mm/a; Vance et al., 2003; Lupker et al., 2013; Scherler et al., 2014). Where necessary, the ^{10}Be accumulated during this transport was then subtracted from the total ^{10}Be sample concentration.

Beryllium-10 production rates were calculated for each pixel of a 30-m resolution ASTER DEM using methods of Dortch et al. (2011) in MATLAB R2017.a. A revised sea-level high-latitude spallogenic production rate of $4.08 \pm 0.23\text{ Be atoms/g/a}$ (Martin et al., 2017; <http://calibration.ice-d.org/>) and ^{10}Be half-life of 1.36 Ma (Nishiizumi et al., 2007) was used, and corrections for topographic shielding for each pixel were made. The ^{10}Be production rate for each investigated catchment was calculated by taking a mean of the production rate values for the DEM pixels. Previous work has shown that shielding by snow can adjust nuclide concentrations in sediment

and boulders by $\leq 20\%$ (Schildgen et al. 2005; Scherler et al., 2014). With snowline elevations below the rockwall slopes that are predominantly north facing, which encourages winter accumulation, snow shielding of the rockwall and supraglacial realm may affect the ^{10}Be concentrations in the medial moraine sediment. Widespread avalanching and minimal snow retention on the rockwall slopes reduce our concern about the effects of snow shielding. Moreover, any adjustment to the nuclide concentrations for snow shielding would be uniform throughout the study areas, and not disrupt the broad trends in the erosion dataset.

Rockwall slope erosion rates were calculated from the ^{10}Be concentrations and catchment production rates using the methods described in detail by Lal (1991), Granger et al. (1996), Balco et al. (2008) and Dortch et al. (2011a). A 1σ uncertainty was propagated through each of the erosion rate calculations.

We calculated the Pearson Correlation Coefficient values (p) between the ^{10}Be concentrations and topographic, climatic and geologic matrices, and conducted a Principle Component Analysis (PCA) to identify and evaluate the possible controls of rockwall slope erosion in the NW Himalaya (The R Core Team, 2018; Supplementary Item 1). A p -value of <0.01 (at $>99\%$ confidence level) was applied. This approach has been successfully applied in other studies to evaluate the nature and magnitude of the environmental response to climatic change (Edwards and Richardson 2004; Sagredo and Lowell, 2012; Seaby and Henderson, 2014). The topographic matrices include: catchment and glacier area, mean catchment, rockwall and glacier slope, catchment 3-km-radius relief, mean catchment elevation, snowline altitude and glacier aspect. Climatic variables include: total annual precipitation (weather stations [as referenced in Table 1] and TRMM [1998–2009]) and temperature (weather stations and CRU2.0 [as referenced in Table 1]), mean rockwall slope temperature and minimum catchment temperature. Catchment specific temperatures were calculated using an adiabatic lapse rate of $7^\circ\text{C}/\text{km asl}$ and methods outlined in

Orr et al. (*in review*). Additional variables such as sample grain size and mean apatite fission track (AFT) cooling ages (referenced in Table 5) were also included within these analyses. The latter enables us to identify any correlation between modern erosion rates and regional denudation histories on the million-year timescale. Upper Bhagirathi was not included in these analyses because the rockwall slope erosion rates characterize an extensive basin system with numerous tributary catchments, rather than a single catchment. The catchment is examined in more detail in the discussion section below. Due to the relatively restricted dataset size and some variability in the precision and resolution of the data, strong yet erroneous associations between nuclide concentrations and catchment matrices can be made. We therefore identify and discuss the most significant parameters in slope erosion with this in mind. P-values were also calculated between nuclide concentrations and catchment parameters for Ladakh, Lahul and Kullu and Garhwal as discrete regions (Supplementary Item 3).

RESULTS

Catchment relief is relatively subdued in the Ladakh region study areas, despite the imposing, high-altitude mountain peaks and rockwalls (>5500 m asl) that mark the headwater limits of each catchment (Table 2). The mean rockwall slopes range between 26.3 ± 12.4 and $35.2\pm 15.5^\circ$. The topography of the Lahul Himalaya is more severe than Ladakh, even with lower mean elevations (<4500 m asl); the investigated catchments are larger (13.9–44.9 km²), and have steeper relative relief (1.2 ± 0.3 – 1.8 ± 0.5 km) and higher mean rockwall slopes (32.8 ± 12.8 – $47.2\pm 11.9^\circ$).

The ablation zone of the Lahul glaciers are either partially or completely covered by debris, whereas in Ladakh, <30% of the glacier surfaces are covered (Fig. 3; Table 3). Beryllium-10 sample concentrations for the Ladakh and Lahul catchments range from 6.1 ± 0.7 to $260.0\pm 12.5\times 10^4$ at/g and 0.5 ± 0.04 to $30.6\pm 1.0\times 10^4$ at/g, respectively (Fig. 2; Table 4). For each catchment, the accumulation of ¹⁰Be during transport from source slopes to medial moraine has a

negligible impact on the derived slope erosion rates; the additional ^{10}Be was smaller than the total concentration error of each sample (Table 4; Supplementary Item 2). In the Batal catchment for example, 0.02×10^4 at/g of ^{10}Be accumulated during transit is subtracted from the total concentrations of G_{Bat1} ($30.6 \pm 1.0 \times 10^4$ at/g) and G_{Bat2} ($3.5 \pm 0.3 \times 10^4$ at/g; Fig. 4). Inherent ^9Be in each sample was either absent or very low. The Chhota Shigri G_{Chh4} sample measured the highest amount of ^9Be in this study at 160.7 ppm, which adjusted the derived erosion rate by $<2\%$.

In the northern Zaskar Range, the ^{10}Be concentrations of the Gopal ($21.0 \pm 0.7 \times 10^4$ at/g) and Stok ($6.1 \pm 0.7 \times 10^4$ at/g) samples infer rockwall slope erosion rates of 0.3 ± 0.04 and 0.9 ± 0.2 mm/a, respectively (Fig. 5; Table 4). Erosion rates of 0.5 ± 0.1 and 0.6 ± 0.1 mm/a for the Amda catchment are derived from ^{10}Be concentrations of $10.8 \pm 0.3 \times 10^4$ and $9.6 \pm 0.3 \times 10^4$ at/g. In central Zaskar, the Karzok samples record ^{10}Be concentrations from 260.0 ± 12.5 to $213.0 \pm 3.5 \times 10^4$ at/g, which yield slope erosion rates between 0.003 and 0.02 mm/a. The adjacent Mentok catchment has a slope erosion rate of 0.2 ± 0.03 mm/a from a ^{10}Be sample concentration of $32.9 \pm 1.2 \times 10^4$ at/g.

The ^{10}Be sample concentrations from Urgos in Lahul (1.7 ± 0.2 , $0.7 \pm 0.0005 \times 10^4$ at/g) infer rockwall slope erosion rates of 2.6 ± 0.4 and 6.5 ± 0.8 mm/a (Table 4). The rate of slope erosion in the Panchi catchment is 0.2 ± 0.1 mm/a, derived from a ^{10}Be concentration of $19.4 \pm 4.5 \times 10^4$ at/g. For Shitidhar, the ^{10}Be concentration and derived erosion rate of G_{Shit1} is $3.2 \pm 0.4 \times 10^4$ at/g and 1.0 ± 0.2 mm/a, respectively. The ^{10}Be sample concentrations range from 30.6 ± 1.0 to $3.5 \pm 0.3 \times 10^4$ at/g and the slope erosion rates range from 0.2 ± 0.02 to 1.3 ± 0.2 mm/a in the Batal catchment. The five samples from the Chhota Shigri catchment have ^{10}Be concentrations between 4.2 ± 1.3 and $1.0 \pm 0.05 \times 10^4$ at/g, which yield slope erosion rates between 1.1 ± 0.4 and 5.0 ± 0.7 mm/a. The ^{10}Be sample concentrations range from $2.0 \pm 0.2 \times 10^4$ to $0.8 \pm 0.1 \times 10^4$ at/g and the slope erosion rates range from 2.0 ± 0.3 to 5.0 ± 1.0 mm/a in Hamtah. Beas Kund records the highest rates of slope

erosion in this study; ^{10}Be concentrations from 0.5 ± 0.04 to $0.8\pm 0.1 \times 10^4$ at/g derive erosion rates between 4.1 ± 0.8 and 7.2 ± 1.1 mm/a (Table 3).

The strongest statistically significant relationships between ^{10}Be concentration and catchment matrices include mean rockwall slope, mean catchment and snowline elevation, total annual precipitation, mean annual temperature and mean AFT cooling age (Table 5). For the region specific analysis, ^{10}Be concentrations have a strong correlation with mean catchment ($p: 5.0 \times 10^{-4}$) and rockwall slope (0.001×10^{-4}) in Ladakh. Catchment parameters do not statistically correlate with nuclide concentrations for the Lahul and Kullu or Garhwal regions (Supplementary Item 3).

DISCUSSION

In view of the inherent complexities of periglacial-glacial environments and the application of cosmogenic nuclide analysis in these settings, the medial moraine ^{10}Be concentrations of each catchment are broadly in concert with one another (Fig. 5). No relationship is apparent between nuclide concentration and proximity of sample location to either a glacier margin or snout. Any internal variability in concentrations within the catchments is likely because the medial moraine sediment is poorly mixed and/or has a non-proportional sediment supply that is dominated by stochastic rockfall events (Small et al., 1997; Muzikar, 2008; Ward and Anderson, 2011). The ^{10}Be concentrations from the Lahul and Kullu catchments are broadly comparable to those from Garhwal, with the exception of Batal and Panchi at the southern margin of the GHS-N unit, where concentrations exceed $3.5\pm 0.3 \times 10^4$ at/g. Nuclide concentrations from the Ladakh and Baltistan region catchments either equal or exceed those from northern Lahul (Table 4; Fig. 2, 5).

The strong variability in physical settings of the catchments prevent any meaningful interpretations or comparisons between specific erosion rates. Moreover, time-averaged nuclide

derived erosion rates come with large uncertainties when characterizing local areas ($\leq 10^1 \text{ km}^2$), which has been shown to underestimate the true rates (Yanites et al., 2009; Willenbring et al., 2013; Sadler and Jerolmack, 2014). Instead, we focus on the broad trends of this first rockwall slope erosion dataset for the NW Himalaya. Rockwall slope erosion becomes progressively less rapid with distance north from the MCT; up to two orders of magnitude difference in erosion exist between Garhwal, Kullu and Lahul, and Ladakh and Baltistan (Fig. 5). The Urgos catchment slightly deviates from this trend with erosion rates of 2.6 ± 0.4 and $6.5 \pm 0.8 \text{ mm/a}$, which are equivalent to those records in Kullu and southern Lahul. The elevated rates may be because the Miyar basin records annual precipitation that exceeds much of Lahul (snowfall: 120–400 cm/a; Patel et al., 2018), and therefore allows for more rapid erosion, or that the low ^{10}Be concentrations are due to the input of fresh debris from the large, steep relief lateral moraines along the Urgos glacier (Fig. 3E, F).

The applicable timescales of this time-averaged dataset, although varied (~ 0.1 –26 ka), mean that the erosion rates encompass recognized shifts in climate, sediment flux, glacier mass balance and seismicity, which themselves operate across various timescales (10^6 – 10^1 years; Barnard et al., 2001; Finkel et al., 2008; Owen and Dortch, 2014; Scherler et al., 2015; Orr et al., *in press*). Between ~ 0.02 and 7 m of lateral rockwall slope erosion is possible for a single millenium in the NW Himalaya. When these rates are extrapolated for the whole Quaternary, ~ 2 km of rockwall retreat is accomplished in the NW Himalaya, which are similar projections to the Sierra Nevada in the Western USA (Brocklehurst and Whipple, 2002).

The magnitude of erosion, particularly in the GHS-S, is therefore sufficient to affect the strength of hillslope-glacier coupling, catchment sediment flux and contribute to topographic change such as the production of relief, the migration of catchment divides, and the reconfiguration of drainage basins (Oskin and Burbank, 2005; Naylor and Gabet, 2007; Heimsath and McGlynn,

2008; MacGregor et al., 2009 *ibid*). The slope erosion rates share a significant association with mean rockwall slope: the greater the mean slope, the more rapid the erosion (Fig. 6A, Table 5). This points to important feedbacks between these variables, where the slope angle and erosion rate limit one another. A similar relationship is recognized between relative relief and slope erosion; where catchments with the high-altitude peaks (>5800 m asl), narrow ridgelines and steep relief (>1.2±0.2 km), record the highest rates of erosion. Part of this is because catchments with rockwall slope erosion rates >1 mm/a have mean rockwall slopes that exceed the 35° threshold, above which slopes are unable to retain regolith, snow or ice (Gruber and Haerberli, 2007; Nagai et al., 2013). This means that rockfall and avalanching is pervasive. More extensive glacier debris cover in these catchments compared to those with slower erosion demonstrate that coupling between slope and glacier is enhanced in catchments with steep accumulation areas, and that slope is important in moderating hillslope debris flux (Regmi and Watanabe, 2009; Scherler et al., 2011; Table 3). Other studies also recognize the importance of slope in landscape change, some of which argue that slope gradients can be used to infer rates of background denudation (Portenga and Bierman, 2001; Finlayson et al., 2002; Burbank et al., 2003; Ouimet et al., 2009; Scherler et al., 2011, 2014).

The magnitude of rockwall slope erosion observed in the NW Himalaya not only demonstrates the importance of lateral erosion through periglacial processes, specifically frost cracking, in high-altitude alpine settings, but also the significance that localized erosion has for understanding wider landscape change (Small and Anderson 1998; Hales and Roering, 2005, 2007; Moore et al., 2009). The rates of slope erosion reflect, in part, the pace of topographic change at the catchment headwaters.

Rates of rockwall slope erosion in Garhwal and Ladakh are either equivalent to, or exceed by up to one order of magnitude, the local catchment-wide erosion and exhumation rates (Fig. 7).

Quaternary exhumation rates have ranged between ~0.1 and 3 mm/a in the study areas (Thiede et al., 2004; Theide and Ehlers, 2013). Catchment-wide rates for Lahul and Kullu are unavailable because much of the region remains glaciated (Owen and Dortch, 2014). Orr et al. (*in review*) caution that comparing these erosion datasets can be problematic as they refer to landscape change through a variety of erosional processes and across various spatial and temporal scales. Nevertheless, the magnitude difference in these rates show that erosion at catchment headwaters in the NW Himalaya largely outpace the wider drainage basins (Oskin and Burbank, 2005; Naylor and Gabet, 2007; Orr et al., *in review*), and that erosion can vary significantly across short distances downstream (Scherler et al., 2014). This is unsurprising as time-averaged rates for small areas such as catchment headwaters and rockwall slopes are sensitive to short-term local change, including single mass wasting events, and are therefore expected to record more rapid rates of erosion than a catchment-wide perspective. The Karzok catchment in central Zaskar, Ladakh deviates from this trend as the rockwall slope erosion either equals or is slower than the catchment-wide erosion and exhumation rates (Fig. 6). The preservation and gradual reworking of landforms and sediment deposits that date to > 400 ka is likely affected by the low background denudation recorded in this region (Hedrick et al., 2011; Dietsch et al., *in revisions*). A possible explanation is that sediment residence times exert a stronger control on the catchment-wide erosion signal in these ancient landscapes, than the scale and various surface processes operating in the applicable area.

Controls of slope erosion

Considerable efforts have been made in recent years to define the parameters that control hillslope stability, and therefore regulate the frequency and magnitude of mass wasting events (Matsuoka, 2001; Ballantyne, 2002; Hales and Roering, 2005; Regmi and Watanabe, 2009; Fischer et al., 2006, 2012 *ibid*). The interactions between topography, climate, hydrological and

geologic setting and cryosphere dynamics are shown to control rockfall activity. Of the catchment parameters which can be defined in the NW Himalaya with some precision, mean rockwall slope as already discussed, mean catchment and snowline elevation, total annual precipitation, mean annual temperature, and mean AFT cooling ages show the strongest correlation with ^{10}Be sample concentrations and/or apparent age, and therefore rockwall slope erosion rates (Fig. 6, 8; Table 5).

The close association between ^{10}Be concentration and mean catchment and snowline elevation is in part due to the scaling of production rates in high altitude settings (Lal, 1991; Balco et al., 2008). However these relationships remain when these concentrations are converted to apparent ages (Fig. 6; Table 5). Accordingly, catchments with the most rapid erosion rates have a greater proportion of the whole catchment above the snowline, and large glacier accumulation areas. Aided by steep slopes that are set in part by erosion, snow and ice entrained with debris is either absent from the rockwall or removed through avalanching. This supports the view that the extent of snow cover, whether set by climatic conditions or surface uplift, is important in moderating mass wasting processes, and can affect the strength of coupling between the rockwall and the glacier system (Scherler et al., 2011, 2014).

Projected surface temperatures of the rockwalls coincide with those considered optimal for mechanical weathering processes (-8 to -3°C), e.g. freeze-thaw, frost cracking and frost wedging (Brozović et al., 1997; Matsuoka and Sakai, 1999; Matsuoka, 2001; Hewitt, 2002; Hales and Roering, 2005; MacGregor et al., 2009; Table 1). The medial moraine sediment characteristics are consistent with sediment from the supraglacial realm, which have detached from source slopes by periglacial weathering processes (Benn and Lehmkuhl, 2000; Schroder et al., 2000; Benn and Owen, 2002; Hambrey et al., 2008; Lukas et al., 2012; Orr et al., *in review*; Table 3; Supplementary Item 4). Rates of periglacial erosion are likely further enhanced by seasonal and/or diurnal thermal variability in exposed bedrock surfaces of our investigated catchments,

which is determined in part by the topographic steepness (Gruber and Haerberli, 2007; Nagai et al., 2013). However, for high elevation catchments (> 4000 m asl) and/or rockwalls, which lack an insulating layer of snow, bedrock surfaces can cool to temperatures below -8 °C, which inhibit further mass wasting (Ward and Anderson, 2011). This is tentatively reflected in the relationship between mean annual temperature and rockwall slope erosion; the catchments with cooler regional temperatures record higher medial moraine ¹⁰Be concentrations and therefore slower erosion rates (Fig. 6). The rockwall debris flux of each catchment is therefore likely influenced by the feedbacks between elevation, temperature and slope.

A strong negative relationship between ¹⁰Be concentration and total annual precipitation supports the view that the distribution and magnitude of Himalayan erosion and denudation is partly a function of orographically focused monsoon rainfall (Bookhagen et al., 2005a; Theide et al., 2004; Bookhagen and Burbank, 2006; Gabet et al., 2006; Wulf et al., 2010; Dey et al., 2016; Fig. 6C, 7). The argument that precipitation provides a first-order control on the frequency and magnitude of mass wasting events in alpine settings is not uncommon (Hovius et al., 2000; Iverson, 2000; Dortch et al., 2009). Work by Eppes and Keanini (2017) argue that the proficiency of mechanical weathering processes such as sub-critical cracking is climate-dependent, and specifically limited by moisture. Although rockwall slope erosion is certainly influenced by the availability of moisture and is sensitive to the microclimatic conditions of each catchment, its distribution throughout the NW Himalaya cannot be fully explained by precipitation. A five-fold decline in precipitation is observed between the first topographic high of the Lesser Himalaya (900±400 m asl) and the interior ranges of the orogen (Bookhagen et al., 2005a,b; Bookhagen and Burbank, 2006; Fig. 7). If precipitation were the primary control of rockwall slope erosion we would expect to find that our maximum erosion rates coincide with maximum rainfall, and that a notable decline in these rates would be observed with distance into the Greater Himalayan interior. However, our results show that this is not the case. Scherler et al (2014) make a similar

observation, where the highest catchment-wide rates in Garhwal are also located north of the precipitation maxima. To further emphasize this point, there is an order of magnitude difference in the rockwall slope erosion rates between the GHS-N and the Tethyan Himalayan, yet a small decline in annual precipitation of < 300 mm.

Since the late Miocene the steep orographic barrier of the Himalaya has restricted the northward advancement of moisture (Bookhagen et al., 2005a; Wulf et al., 2010), therefore preventing any subsequent major shift in the overall intensity or distribution of precipitation (Bookhagen et al., 2005a; Bookhagen and Burbank, 2010; Boos and Kuang, 2010; Thiede and Ehlers, 2013). The overall pattern in slope erosion throughout the NW Himalaya is therefore unlikely to be an artifact of a previous climatic regime, despite short-term fluctuations in monsoon strength during the Quaternary potentially affecting rockfall activity on the catchment scale (Thompson et al., 1997; Gupta et al., 2003; Fleitmann et al., 2003; Demske et al., 2009). One major concern in evaluating the role of climate in long-term landscape change is that the denudation records are averaged across million year timescales and are therefore unable to account for the importance or variations in the Indian summer monsoon (Bookhagen et al., 2005a; Thiede and Ehlers, 2013). This study is able to show that erosion records that reflect landscape change on timescales that would be sensitive to fluctuations in monsoon strength (10^{2-5} years), i.e. slope and catchment-wide erosion, are not unilaterally controlled by precipitation.

Beryllium-10 sample concentrations and therefore rockwall slope erosion rates are most closely associated with regional AFT cooling ages (Fig. 6D, 7; Table 5). Much attention has been paid to understanding the patterns of cooling ages and exhumations rates in the Himalaya, and the feedbacks between tectonics and climate that are responsible for the distribution and intensity of Himalayan denudation across million year timescales (Schelling and Arita, 1991; Srivastava and Mitra, 1994; Thiede and Ehlers, 2013). Many studies have argued that this denudation is

primarily governed by climate; orographic precipitation causes rapid erosion and exhumation along the Himalayan front and Lesser Himalaya (Zeitler et al., 2001; Thiede et al., 2004; Grujic et al., 2006; Biswas et al., 2007; Sharma et al., 2017; Kumar et al., 2018). However, young AFT ages (<10 Ma) and rapid rates of exhumation throughout the Lesser Himalaya and GHS-S instead reflect a close interaction between tectonics, denudation and monsoon-enhanced erosion, rather than just the latter (eg. Wobus et al., 2003; Thiede et al., 2004; Vannay et al., 2004). Coupling between climate and tectonics becomes less evident further into the Greater Himalayan interior; while the GHS-N becomes progressively more arid, the AFT ages remain <17 Ma and exhumation rates < 5mm/a (Thiede and Ehlers, 2013; Schlup et al., 2003; Fig. 7). The pattern in AFT ages and inferred exhumation histories for the NW Himalaya, like our rockwall slope erosion dataset, cannot therefore be fully explained by precipitation. Instead there is the growing argument that the patterns in Himalayan denudation are instead a function of tectonically controlled rock uplift; the result of crustal wedge deformation from the Indo-Eurasian collision and the flat-ramp-flat geometry of the Main Himalayan Thrust (e.g. Burbank et al., 2003; Bollinger et al., 2006; Herman et al., 2010; Robert et al., 2011; Godard et al., 2014). The lateral and vertical transport of rock over the ramp since the late Miocene has resulted in rapid and continuous exhumation, and the generation of steep topographic relief (Cattin and Avouac, 2000; Godard et al., 2004; Lavé and Avouac, 2000, 2001). Young AFT cooling ages and rapid rates of exhumation are therefore focused throughout the Lesser Himalaya and GHS-S (Fig. 7). This is consistent with the pattern in rockwall slope erosion, therefore indicating that tectonically driven rock uplift throughout the NW Himalaya is likely to provide a major control on patterns of denudation since the late Paleogene and late Quaternary records of erosion (Scherler et al., 2014; Orr et al., *in review*). Precipitation would therefore come as a secondary control.

Principle Component Analysis indicate that ~68% of the variance observed in rockwall slope erosion rates in the NW Himalaya can be explained by the six parameters discussed above (mean

rockwall slope, mean catchment and snowline elevation, total annual precipitation, mean annual temperature and mean AFT age; Fig. 8). Other parameters that were either less statistically significant or could not be included in these analyses are also likely to contribute slope erosion (Table 5). Rockwall lithology, rock strength and mass quality, and jointing and structure affect the thresholds for mass wasting and have been shown to govern hillslope debris flux and rates of erosion (Hallet et al., 1991; Augustinus, 1995; Anderson, 1998; Hales and Roering, 2005; MacGregor et al., 2009; Fischer et al., 2010). Rockfall activity in the investigated catchments is therefore very likely affected by the erodability of the rockwall and the periglacial processes acting upon it (Heimsath and McGlynn, 2008; Eppes and Keanini, 2017). The significance of this parameter in patterns of slope erosion on the regional scale is however less clear. Previous work has argued that the difference in rock strength between the crystalline sequences of the Lesser and Greater Himalaya is negligible, and therefore has little influence upon the denudation histories of the orogen (Burbank et al., 2003; Scherler et al., 2011, 2014).

Studies throughout High Asia have shown that geomorphic change, specifically mass wasting events, are closely associated with neotectonism including stochastic earthquakes and/or persistent microseismicity (Hovius et al., 2000; Rajendran et al., 2000; Bali et al., 2003; Menunier et al., 2008; Dortch et al., 2009; Lupker et al., 2012). The frequency of rockfall events and therefore rates of slope erosion in our investigated catchments is therefore likely to be influenced in part by local tectonic activity.

A further candidate for rockwall slope erosion control is glaciation and glacial erosion; vertical incision and the debuitting of slopes lead to enhanced slope instability and failure (Naylor and Gabet, 2007; Heimsath and McGlynn, 2008; MacGregor et al., 2009; Fischer et al., 2010). Large, erosive temperate glaciers occupy catchments with rapid rates of rockwall slope erosion, while slower rates are from catchments with less erosive, sub-polar glaciers (Owen and Dortch, 2014).

The local glacial records for each investigated catchment confirm shifts in glacier mass balance throughout the Holocene (Saha et al., 2018; Table 1). Past retreat and expansion of glacier ice may have contributed to the evolution of the rockwalls; the downwasting of ice may encourage the unloading of slope debris, while a greater glacier volume may see an increase in glacial erosion processes acting upon the slope (Fischer et al., 2006; 2010, 2012).

Rather than a single control, we have demonstrated that rockwall slope erosion is instead more likely the result of longstanding feedbacks between topography, surface processes, climate and tectonics. This supports the initial findings of Orr et al. (*in review*), where the evolution of the rockwalls in the present day is determined by the unique expression of these feedbacks within each catchment. However, our erosion dataset does not account for any variability in the drivers or rate of rockfall activity throughout the applicable timescales (0.1–26 ka). The relative importance of each of these various parameters in slope erosion will therefore likely vary across spatial and temporal scales. The correlation between rockwall erosion and slope, e.g., which is recognized for the whole dataset, is not apparent in either Lahul and Kullu or Garhwal, if they are considered discrete regions. Only in Ladakh and Baltistan do the steepest catchment and rockwall slopes record the most rapid rates of erosion. No catchment parameters have strong correlations with slope erosion for either Lahul and Kullu or Garhwal. This may be because slope erosion is sensitive to other undefined parameters such as glaciation, or that deciphering erosion controls is not possible due to the inherent complexities of glaciated catchments in the NW Himalaya. An alternative explanation is that once a threshold for a parameter is met, slope erosion is then predominantly limited by this one parameter. During a period of enhanced rainfall or monsoon storm along the Himalayan front for example (Bookhagen et al., 2005b; Clift et al., 2008), catchments with strongly contrasting physical settings may display similar rockfall activity. The rainfall magnitude is sufficient to override any resistance to mass wasting, such as a strong, non-erosive rock type or shallow, low relief slopes. When averaged over time, these catchments will

share a similar record of erosion. This may offer an explanation for why single high-magnitude events such as these, are viewed to be responsible for a significant proportion of the total landscape change in a mountain environment (Hasnain 1996; Craddock et al., 2007; Wulf et al., 2010).

We have suggested that slope erosion is largely influenced by catchment-specific conditions that vary over temporal and spatial scales. However, our study is able to demonstrate that the broad spatial patterns in this erosion follow long-term trends in denudation throughout the NW Himalaya, and are therefore broadly controlled by tectonically driven rock uplift. Precipitation is considered a secondary control. This suggests that periglacial rockfall processes are part of the erosional response to structural change throughout the Himalayan-Tibetan orogen, and play a significant role within topographic change at catchment headwaters and the mass balance of the orogen. Identifying a more significant tectonic control to landscape change than climate is becoming more common; work in the wider Himalaya and the northern Bolivian Andes suggest that denudation patterns do not follow gradients in precipitation (Burbank et al., 2003; Gasparini and Whipple, 2014; Godard et al., 2014; Scherler et al., 2014).

CONCLUSION

Rates of rockwall slope erosion are defined for 12 catchments in northern India, NW Himalaya and range between 0.02 and 7.2 ± 1.1 mm/a. Rockwall slope erosion largely outpaces local catchment-wide erosion and exhumation, and is sufficient to affect catchment sediment flux, glacier dynamics and topographic change, such as the production of relief, the migration of catchment divides and the reconfiguration of drainage basins.

Erosion rates become progressively less rapid with distance north from the MCT; up to two orders of magnitude difference in erosion rates are observed between the Garhwal, Kullu and Lahul, and Ladakh and Baltistan. Rather than a single control, rockwall slope erosion on a catchment-by-catchment basis is largely influenced by longstanding feedbacks between topography, geology, surface processes, climate and tectonics. The relative roles of these parameters are likely to vary over various spatial and temporal scales.

Our study demonstrates that like records of denudation in the NW Himalaya, the broad trend in rockwall slope erosion cannot be fully explained by the distribution of precipitation. Instead slope erosion can be considered part of the erosional response to tectonically driven uplift, the product of Indo-Eurasian convergence and the geometry of overthrusting. The distribution and magnitude of erosion on geomorphic (10^2 – 10^5 years) and geologic (10^6 years) timescales in the NW Himalaya therefore indicates that tectonics, rather than climate, provide a first-order control on landscape evolution. Our study also demonstrates the importance of lateral rockwall slope erosion via periglacial processes in helping set the pace of topographic change at catchment headwaters of high altitude and high relief mountain ranges, and the significance that localized erosion has for understanding wider landscape change.

ACKNOWLEDGMENTS

ENO thanks the University of Cincinnati for providing tuition and stipend to support this work as part of ENO's doctoral thesis and the processing of samples for ^{10}Be dating. ENO would like to thank PRIME Laboratories at Purdue University for a seed grant for AMS measurements. ENO also extends thanks to National Geographic, the Geological Society of America and the Graduate Student Governance Association, University of Cincinnati for research grants to conduct fieldwork.

Fig. 1. Overview of the study area in the NW Himalaya. Hillshade map is overlain by total annual precipitation (TRMM 2B31; Bookhagen and Burbank, 2006). Major faults from Hodges (2000) and Schlup et al. (2003). White circles: investigated catchments of this study. Gray circles: location of published slope erosion rate studies (Seong et al., 2009; Scherler and Egholm 2017; Orr et al., *in review*). Squares with gray fill: catchment-wide erosion rate studies (Vance et al., 2003; Dortch et al., 2011; Schlerer et al., 2015; Dietsch et al., 2015, 2019). Inset map illustrates the location (black polygon) of the study areas (relief map with swath polygons [bold polygons S1, 2, 4, 5 are referred to in Fig. 7] modified from Bookhagen and Burbank 2006).

1: 3-km-radius relative relief

2: Slope calculated from 0.001km² catchment grid cells

3: Strahler (1952) Hypsometric Index (mean elevation- min elevation/relief)

4: Mean of equilibrium line altitudes (ELA)/snowline elevation (SE) calculated using Area-altitude (AA), Area-accumulation ratio (AAR: 0.4,0.5,0.6) and Toe-headwall ratio (THAR: 0.4,0.5) methods from Benn et al. (2005) and Osmaston (2005).

Table 3. Medial moraine morphology and sediment descriptions

	D.C¹	Medial moraine description	Supraglacial diamict description
Gopal	R	-Subdued moraine ridge; heterogeneous debris thickness (<5 mm–2 m).	-Sandy-boulder gravels with silt matrix; angular-sub angular clasts of leucogranite and granitic gneiss.
Stok	R	-Subdued moraine ridge; heterogeneous debris thickness (<5 mm–2 m); some soil development.	-Bouldery gravels; angular-sub angular clasts of leucogranite, granitic gneiss and schist.
Amda	R	-Moraine deposits along northern flank of Amda Kangri; heterogeneous debris thickness (<30 cm); some soil development and xerophytic shrubs.	-Sandy gravels with silt matrix containing interstitial ice; angular-sub angular clasts of leucogranite and schist.
Karzok	R	-Subdued moraine ridge (<10 m wide); heterogeneous debris thickness (<5 mm–10 m)	-Bouldery gravels with sandy matrix; very angular- sub angular clasts of leucogranitic, gneiss and schist.
Mentok	R	-Moraine deposits at Mentok Kangri snout; heterogeneous debris thickness (<5 mm–3 m).	-Bouldery gravels with sandy matrix; very angular- sub angular clasts of leucogranitic, gneiss and schist.
Urgos	C	-Distinct, steep relief medial moraine ridges; depressions and ice collapse features; heterogeneous debris thickness (<5 mm–5 m); discontinuous soil development, tundra vegetation and large boulders (>2–0.25 m) along and slightly offset from ridges.	-Sandy-boulder gravels with silt matrix containing interstitial ice; angular-sub angular clasts of leucogranite and granitic gneiss.
Panchi	C	-Steep relief medial moraine ridge; surface depressions; large ice cliff at glacier snout; restricted soil development.	-Sandy gravels with a silty-sand matrix; angular-sub rounded clasts of schist.
Shitidhar	P	-Subdued moraine deposits; heterogeneous debris thickness (<5 mm–2 m).	-Gravelly boulders with sandy matrix; very angular- angular clasts of leucogranitic, gneiss and schist.
Batal	C	-Steep relief medial moraine ridge; ice cliffs; heterogeneous debris thickness (<5 mm–2 m); restricted soil development.	-Sandy-boulder gravels with silt matrix, angular-sub angular schistose clasts.
Chhota Shigri	C	-Distinct moraine ridges along length of ablation zone; heterogeneous debris thickness (<1cm–1 m); large boulders (>5 m) located along moraine ridge; soil development and tundra vegetation.	-Bouldery gravels with sandy-silt matrix, angular-sub rounded clasts of granite, granitic gneiss and schist.
Hamtah	C	-Distinct moraine ridges along length of ablation zone; heterogeneous debris thickness (<5mm–>5 m); soil development and tundra vegetation.	-Bouldery gravels with sandy-silt matrix, angular-sub rounded clasts of granitic gneiss and schist.
Beas Kund	P	-Steep relief medial moraine ridge, heterogeneous debris thickness (<5mm– 2 m); soil development restricted to moraine ridges	-Sandy-boulder gravels; angular- sub angular clasts of granite and gneiss.

1: Debris cover: C- Complete debris coverage of the glacier ablation zone; P- Partial coverage (>30% of ablation zone surface); R- Restricted coverage (<30% of ablation zone surface)

Table. 4. Medial moraine sample details, ¹⁰Be concentrations and interpreted slope erosion rates for the study areas.

ABSTRACT

The timing of surface abandonment for ten alluvial/debris-flow fans across contrasting climatic settings in the NW Himalaya of northern India are defined using cosmogenic ¹⁰Be surface exposure dating. Debris-flow fans in the Garhwal, Kullu and Lahul regions of the monsoon-influenced Greater Himalaya were largely abandoned during the Mid–Late Holocene. Large alluvial fans and smaller debris-flow fans in the semi-arid Ladakh region of the Greater and Tethyan Himalaya have surface ages which extend throughout the last glacial. Regional events of landform abandonment and incision are defined for the monsoon-influenced western Himalaya ranges (MWHR) and the semi-arid western Himalaya ranges (SWHR) over the past ~120 ka. In the MWHR and SWHR these regional events are limited to the Holocene and from ~40 ka, respectively. The timing of fan surface abandonment and regional landform abandonment events coincide with periods of weakening monsoon strength and cooling, and local and regional glacier advances. The nature and timing of fan stabilization and abandonment in the NW Himalaya is determined by the interaction between climate and internal catchment dynamics including

sediment supply and topography. Regional incision events from the MWHR and SWHR regions are recognized across various climatic conditions due to the ubiquitous nature of erosion in mountain settings. Climate-driven processes and glaciation are important drivers in fan sedimentation, catchment sediment flux and the topographic evolution of the NW Himalaya during the late Quaternary.

Keywords: sediment flux; glaciation; climate; topographic controls; cosmogenic isotopes

INTRODUCTION

Alluvial/debris-flow fans are widespread throughout mountain environments. These landforms radiate from locations at points of gradient lowering along mountain fronts and where catchments become unconfined, invariably at the mouth. In high-altitude, high-relief settings such as the Himalayan-Tibetan orogen, alluvial/debris-flow fans serve as temporary stores of poorly sorted deposits including debris-flow, glaciofluvial, fluvial, lacustrine and aeolian sediment (Ballantyne 2002a,b; Barnard et al., 2006b). Alluvial/debris-flow fans are not simply fluvial in nature; debris/mud flow, snow avalanching and other diffusive hillslope processes also contribute to their formation (Ballantyne 2002a, Nicholas and Quine 2007). We refer to these landforms as ‘fans’ in our study.

In the Himalayan-Tibetan orogen, most fans are understood to form and evolve as part of the landscape response to a shift in climate or environmental conditions (Owen and Sharma 1998; Kumar Singh et al., 2001; Barnard et al., 2004a,b, 2006a,b; Srivastava et al., 2008). Studies have shown that fans frequently form as the result of enhanced catchment sediment flux following deglaciation. The climate-driven downwasting and retreat of glacier ice causes the unloading of hillslope debris, and the reworking and redistribution of glacial sediment to the catchment

mouth. Fans in the Himalaya are found to aggrade in this way on timescales of 10^4 – 10^1 years after the onset of deglaciation (Owen and Sharma 1998; Watanabe et al., 1998; Ballantyne 2002a).

Shifts in catchment sediment flux and the aggradation of fans can also be the result of processes and events that enhance hillslope instability. The regeneration or readvance of a glacier can exacerbate instabilities by steepening and/or debuitressing hillslopes through glacial erosion (Watanabe et al., 1998; Ballantyne et al., 2002a; Barnard et al., 2006b; Hewitt, 2009). Further adjustments to slope stability can occur through periglacial weathering processes, permafrost degradation, changes in runoff regime and extreme storm and flood events (Gruber and Haeberli 2007; Hales and Roering 2007; Eppes and McFadden 2008; Heimsath and McGlynn 2008). In addition to climate, other variables that are also likely to contribute to the formation and evolution of fans include: sediment supply, source catchment lithology, seismic events and changes to base level (Ritter et al., 1995; Pope and Wilkinson 2005; Hobbey et al., 2010; Scherler et al., 2014). Deciphering the relative role of any one of these variables in the development of these landforms is challenging in rapidly denuding mountain settings such as the Himalaya, particularly as each factor will likely vary over space and time.

There are few quantitative studies that define the timing of fan development and stabilization in the Himalaya. Our understanding of the evolution of these landforms and the wider catchment, and the influence of climate and/or tectonism within these sedimentary systems is therefore incomplete. Improvements in dating methods, particularly cosmogenic nuclide surface exposure dating, enable better constraints on the age of fan surfaces (Dühnforth et al., 2007; Blisniuk et al., 2012; Cesta and Ward 2017). Cosmogenic nuclide surface exposure ages define the timing of fan surface abandonment, and a period of landform stability following its formation across timescales of 10^4 – 10^1 years (Pope and Wilkinson 2005; Owen et al., 2014).

Well-preserved fans in the NW Himalaya provide an excellent opportunity to assess the controls of fan formation in a high-relief mountain setting, as well as evaluate how these controls may vary between areas of contrasting climatic regime. We report 18 new and 29 recalculated ^{10}Be fan surface ages for a suite of ten fans across the Greater Himalaya ranges of northern India. This study focuses on three new study areas: the Kullu and Chandra valleys in the monsoon-influenced Kullu and Lahul regions in Himachal Pradesh, and the Karzok valley is located in semi-arid Ladakh in Jammu and Kashmir (Fig. 1). We also revisit the study areas of Tangtse valley in Ladakh, and the Bhagirathi and Gori Ganga valleys in the warm-wet Garhwal region of Uttarakhand. We compare the fan surface ages in our study with local and regional climate and glacial records to evaluate the contributions of climate and climate-driven surface processes in the timing of fan aggradation and stabilization in the NW Himalaya, throughout the late Quaternary.

Regional landform abandonment and incision events are defined for the monsoon-influenced Lesser and Greater Himalaya, and the semi-arid interior ranges of the Greater and Tethyan Himalaya using geomorphic records throughout the NW Himalaya (Fig. 1). This record is compared to the fan surface ages of our study to explore possible patterns or times of regional landscape change in response to climate. We also discuss the effect of preservation bias within geomorphic evidence in the understanding of landscape change throughout the NW Himalaya.

REGIONAL SETTING

The regional geologic setting of the study area is the consequence of the continued collision and partial subduction between the Indian and Eurasian continental lithospheric plates, commencing at ~55 Ma (Searle et al., 1997). In the NW Himalaya, the Indus-Tsangpo Suture Zone marks the collision zone between these continental plates and the northern boundary of the Tethyan Himalaya. Deformation driven crustal shortening from the early Miocene to the Pleistocene

initiated the development of a series of foreland propagating thrust systems that divide the Himalayan lithotectonic units south of the Tethyan Himalaya, into the High Himalaya crystalline sequence, the Lesser Himalaya sequence, sub-Himalaya and foreland basin (Searle, 1986; Steck et al., 1998; Schlup et al., 2003; Vannay et al., 2004; Thakur et al., 2014).

The climate in the NW Himalaya is primarily governed by the mid-latitude westerlies that bring most of the precipitation during the winter from the Mediterranean, Black and Caspian seas (Mölg et al., 2013), and the south Asian summer monsoon (SASM) that advects moisture from the Indian Ocean bringing enhanced summer precipitation to the high altitude southern frontal ranges of the orogen (Benn and Owen 1998, 2002; Bookhagen and Burbank 2006, 2010; Owen 2009). The imposing orographic barrier of the Himalaya creates a steep precipitation gradient, perpendicular (S–N) to the strike of the mountain belt (Qiang et al., 2001; Liu and Dong, 2013). The northward decline in annual precipitation today falls from ~1500–3000 mm in the Lesser and Greater Himalaya ranges to <150 mm in the interior of the Tibetan Plateau (TRMM 1998–2005, Bookhagen and Burbank, 2006). Strong variability in climate throughout the late Quaternary is considered to have a significant influence upon the rate and magnitude of landscape change (Prell and Kutzbach, 1987; Gasse et al., 1996; Shi et al., 2001; Bookhagen et al., 2005; Bookhagen and Burbank, 2006; Wulf et al., 2010) and nature and timing of glaciation (Owen and Dortch, 2014) in the Himalayan-Tibetan orogen.

There is growing contention around whether the morphostructural and landscape evolution of the mountain belt is the result of climate-topography interactions and/or underlying tectonism. Most studies argue that the spatial distribution of erosion is a function of orographically focused monsoon rainfall (Bookhagen et al., 2005; Bookhagen and Burbank 2006; Gabet et al., 2006; Wulf et al., 2010). This relationship is not straightforward however because the distribution and magnitude of precipitation on the regional scale varies both spatially and temporally, and local

microclimates are retained throughout individual mountain ranges. Moreover, sporadic heavy rainfall has been argued to govern the sediment flux of Himalayan catchments (Hasnain 1996; Craddock et al., 2007; Wulf et al., 2010). The opposing view is that patterns in erosion are instead determined by structurally controlled rock uplift (Lavé and Avouac 2001; Burbank et al., 2003; Thiede et al., 2004; Scherler et al., 2014).

Most Greater Himalaya glaciers today are large, temperate and melt-dominated, and are fed by monsoonal precipitation (Benn and Owen, 2002; Su and Shi, 2002). Glaciers in the semi-arid Greater Himalaya are usually small (1–10 km²) cold-based sub-polar types: precipitation-sensitive and sublimation-dominated (Benn and Owen, 2002). Evidence of three to four glacial stages per catchment is typically preserved throughout the western Himalaya (Owen and Dortch, 2014). The glacial records of the NW Himalaya are synthesized by the following regional chronostratigraphies: the semi-arid western Himalayan-Tibetan orogen stages (SWHTs) of Dortch et al. (2013), monsoonal Himalayan-Tibetan stages (MOHITs) of Murari et al. (2014), and Himalayan Holocene stages (HHs) of Saha et al. (2018). Dortch et al. (2013) and Owen and Dortch (2014) argue that the nature, timing and forcing of glaciation varies over short distances (10¹–10² km) within individual mountain ranges. Broadly, glacier advances in the NW Himalaya are moderated by monsoon strength (Owen and Sharma 1998; Watanabe et al., 1998). Our study areas were selected because the local glacial successions have been dated using cosmogenic nuclides (Table. 1).

The Kullu valley study area is located on the southern slopes of the Pir Panjal Range of the Greater Himalaya in the Kullu district of Himachal Pradesh (Fig. 1; Table 1). This large transverse drainage system extends ~60 km from the source of the Solang Nala and Beas rivers (~3400 m asl) to the village of Larji (~1000 m asl). The study area is limited to the upper reaches

of the Kullu valley (>1700 m asl) where bajada-style fan complexes sourced from the eastern and western tributaries occupy the valley (Owen et al., 1995).

The Chandra valley is a large longitudinal drainage system in the Lahul-Spiti district of Himachal Pradesh, in the rainshadow of the Pir Panjal Range (Fig. 1; Table 1). The study area extends along the northwest flowing Chandra River from Koksar (32.4141°N, 77.2351°E) to Sissu (32.4805°N, 77.1220°E), and is characterized by highly dissected fans along the valley floor.

The Karzok valley is located in the high altitude semi-arid desert of the Zaskar Range, Ladakh in Jammu and Kashmir (Fig. 1; Table 1). The study area is composed of a series of northeast trending tributary catchments draining the Rupshu Massif. A broad bajada extends along the flank of the massif.

METHODOLOGY

Our investigated valleys have small glaciated and non-glaciated tributary catchments that contain a wealth of well-preserved Quaternary deposits and landforms. Fans composed of diamicts and gravels are particularly abundant in these study areas (Derbyshire and Owen, 1990; Owen et al., 1995; Barnard et al., 2004a,b; Barnard et al., 2006b).

Field Methods

Detailed geomorphic maps of each study area were made in the field aided by Landsat Enhanced Thematic Mapper Plus (ETM+) imagery (30 m resolution), topographic maps generated from Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) global digital elevation models (V002, 30 m resolution), and Google Earth imagery. Landforms and sediments

were described and differentiated using geomorphic and sedimentological methods and criteria of Benn and Owen (2002).

Topographic and geomorphic metrics for the study areas and investigated fans were calculated from an ASTER V002 derived DEM (30 m resolution) using the Spatial Analyst toolbox in ESRI's ArcMap 10.1 (Table 1).

Fans in each study area were assigned names based on their source catchment and where appropriate were numbered from oldest to youngest (1 to n) based on their morphostratigraphic position within the catchments (Hughes et al., 2005; Hughes, 2010). As an example, $Qf_{GOMUCHE03}$ (Qf = Quaternary fan) is located furthest downstream (subscript 03) from the Gomuche tributary catchment (subscript GOMUCHE).

The best-preserved fans with clearly defined proximal and distal zones with little evidence of surface denudation, deflation or human modification were selected for further investigation and ^{10}Be dating. The investigated fans include: Qf_{SARAI} from the Kullu valley; Qf_{SISSU} and Qf_{TELING} from the Chandra valley; and $Qf_{MENTOKa}$ and $Qf_{MENTOKb}$ from the Karzok valley.

Three to five boulders of quartz-bearing lithologies were sampled for ^{10}Be dating on each fan surface. Approximately 500 g of rock with a thickness of 1–5 cm was removed from each boulder surface using a hammer and chisel. The sampled boulders were described and photographed (Appendix 1), and their locations recorded using a handheld Garmin Etrex 30 GPS unit. Topographic shielding was measured at 10° azimuths from the boulder surface to the horizon using a compass and inclinometer.

Large tabular boulders with varnish and/or lichen cover, well set into the fan surface were

preferentially selected for sampling; sampling large boulders reduces the likelihood of selecting ones that have recently toppled or been exhumed (Benn and Owen, 2002; Heyman et al., 2011). Boulders were avoided if there was with evidence of strong weathering, pitting, fracturing, exfoliation or shielding from regolith. Likewise, boulders adjacent to or within areas with evidence of human modification of the landscape were not sampled. Boulders were only sampled from the distal zones of each fan to restrict the likelihood of them being derived from adjacent slopes through rockfalls. Boulders in ephemeral channels were also avoided.

The ^{10}Be age of each fan surface was defined by the range of boulder exposure ages. The age range defines the timing of the abandonment of the fan surface, and cessation of fan aggradation (Pope and Wilkinson 2005; Owen et al., 2014; Cesta and Ward 2016). A broad range of ^{10}Be ages may be the result of inheritance, boulder weathering, toppling or shielding, or that multiple sedimentation events characterize the fan surface (Zehfuss et al., 2001; Blisniuk et al., 2012; Hedrick et al., 2013). No statistical treatment of the ^{10}Be ages was possible due to the restricted size of the dataset, and distribution of ages for each landform.

Laboratory Methods

Crushing and sieving of the rock samples, quartz isolation, dissolution, chromatography, isolation of Be and the preparation of BeO was performed at the Geochronology Laboratories at the University of Cincinnati, using the chemical procedures and community standards of Kohl and Nishiizumi (1992) and Nishiizumi et al. (1994), modified by Dortch et al. (2009). The isolated BeO was mounted onto steel cathodes and the $^{10}\text{Be}/^9\text{Be}$ sample ratios were measured using accelerator mass spectrometry (AMS) at the Purdue Rare Isotope Measurement Laboratories (PRIME) at Purdue University (Sharma et al. 2000).

¹⁰Be Fan Exposure Ages

The ¹⁰Be boulder exposure ages were calculated using the Cosmic Ray Exposure program calculator (CREp) of Martin et al. (2017), using the LSD scaling model (Lifton et al., 2014) with the ERA40 atmospheric model (Uppala et al., 2005) and Lifton VDM 2016 geomagnetic database. This calculation scheme accounts for nuclide-specific production rate sensitivities to temporal and spatial variability in geomagnetic and solar inputs (Lifton et al., 2014), and has been successfully applied throughout the NW Himalaya, particularly for the Holocene (Orr et al., 2018; Saha et al., 2018). Published ¹⁰Be ages of the revisited Garhwal (Barnard et al., 2004a,b) and Ladakh (Brown et al., 2002, 2003; Dortch et al., 2011c) fans were recalculated using these same methods, to allow for comparisons between fan records. The exposure ages were calculated assuming zero erosion. The effect of erosion is considered negligible owing to the very low 0.5–2.3 m/Ma rates measured throughout the Ladakh Range of northern India (Dortch et al., 2011b; Dietsch et al., 2015).

Regional landform abandonment and incision events in the NW Himalaya

Probability density functions of phases of landform abandonment and incision for the monsoon influenced Lesser and Greater Himalaya ranges (MWHR: monsoon western Himalayan ranges) and semi-arid interior ranges of the Greater Himalaya and Tethyan Himalaya (SWHR: semi-arid western Himalayan ranges) were defined by numerically dated river terrace, strath terrace and fan surfaces from existing geomorphic studies (Fig. 1). Previously published numerical cosmogenic ages were recalculated using the same calculation scheme as was used for our new fan ages. The MWHR region includes the Lahul, Kullu, Simla, Uttarkashi and Garhwal districts of northern India, whilst SWHR spans the Ladakh region of northern India and the Karakoram ranges of northeastern Pakistan. Regional events in landform abandonment and incision are defined by ≥ 3 ages. Landform abandonment events refer to times of restricted sedimentation where landforms stabilize.

LANDFORM DESCRIPTIONS

The Qf_{SARAI} (32.3095°N, 77.1568°E) fan in the Kullu valley study area is sourced from the Sarai tributary; a steep relief unglaciated catchment with a parallel drainage system. The fan is located at the confluence between the Solang Nala and Beas River at ~2300 m asl (Table 2, 3; Fig. 2). The source catchment of the Qf_{SISSU} fan (32.4827°N, 77.1176°E) in the Chandra valley study area is located adjacent to the Sissu Nala catchment (Fig. 3A–C). This steep relief catchment has preserved evidence of past glaciation, but presently is not glaciated. Qf_{TELING} (32.4357°N, 77.1926°E) is sourced from the Teling tributary, ~6 km northwest from Koksar (Fig. 3D–F). This glaciated amphitheater preserves an abundance of landforms and sediment deposits including moraines, talus and mass movements. In the Karzok valley study area, $Qf_{MENTOKa}$ (32.9647°N, 78.2381°E) is the most easterly fan of the bajada, sourced from a Mentok catchment that has a cirque glacier. A similar morphology is shared by the second Mentok tributary catchment located directly adjacent to, and to the northwest of the first: the source catchment for $Qf_{MENTOKb}$ (32.9701°N, 78.2301°E; Table 2, 3; Fig. 4).

RESULTS

New and recalculated fan surface ^{10}Be Ages

Fan surfaces in the Kullu and Chandra valley study areas have ^{10}Be boulder ages <12 ka, the majority <4 ka. ^{10}Be ages for the Karzok valley fan surfaces range between ~110 and 12 ka (Fig. 5; Table 4; Appendix 1).

The Kullu valley Qf_{SARAI} fan surface has ^{10}Be ages between 7.8 ± 1.1 and 2.8 ± 0.2 ka (uncertainties for all ages are quoted to 1σ). The Qf_{SISSU} and Qf_{TELING} fan surfaces in the Chandra valley study

area have ^{10}Be age ranges of 10.9 ± 0.6 – 2.4 ± 0.3 ka and 11.8 ± 1.6 – 0.6 ± 0.1 ka, respectively. In the Karzok valley study area, Qf_{MENTOKa} has ^{10}Be ages between 110.8 ± 2.2 and 64.5 ± 0.5 ka, whilst the $Qf_{\text{MENTOKb}}fan$ surface has ages from 66.1 ± 1.3 to 12.6 ± 0.3 ka. No ages are discounted from the dataset because the restricted number and distribution of ^{10}Be ages for each landform prevents the identification of age outliers.

The recalculated ages for the *Rilkot1* fan surface in the Gori Ganga valley, northeast Garhwal range from 1.8 ± 0.2 to 0.9 ± 0.1 ka (Appendix 2). In the Bhagirathi valley, *Gaumukh1* and *Gaumukh2* fan surfaces have ^{10}Be ages that range from 5.5 ± 0.2 to 3.1 ± 0.2 ka and 1.5 ± 0.3 to 1.2 ± 0.2 ka, respectively. Additional fan surfaces with only one exposure age were also recalculated for this valley (*Bhuj Kharak1*: 3.27 ± 0.47 ka; *Kedar Kharak1*: 9.8 ± 0.6 ka; *Rudugairal*: 7.8 ± 0.5 ka), but are not referred to herein. The surface ages for the northern Ladakh *Tangtse1* and *Tangtse2* range from 38.6 ± 2.6 to 19.0 ± 1.5 ka and 14.3 ± 1.5 to 2.1 ± 0.2 ka, respectively.

Regional landform abandonment and incision events for the NW Himalaya

Records of landform abandonment are recognized in the MWHR region throughout the past ~ 50 ka, with regional events at 1.4 ± 0.5 and 0.6 ± 0.2 ka (Fig. 6; Appendix 3, 4). Records of incision extend from ~ 70 to 0.6 ka, with regional incision events at 6.9 ± 3.7 , 3.6 ± 1.0 , 1.8 ± 0.6 and 1.0 ± 0.1 ka. In the SWHR region of the NW Himalaya, records of landform abandonment extend over the past 56 ka and >110 ka. Regional events occur at 31.5 ± 5.1 and 20.0 ± 5.3 ka. Records of incision are recognized throughout the past ~ 120 ka, with regional events occurring at 35.9 ± 5.8 , 13.7 ± 3.9 and 2.2 ± 1.7 ka.

DISCUSSION

The *Rilkot1* (1.8 ± 0.2 – 0.9 ± 0.1 ka), *Gaumukh1* (5.5 ± 0.3 – 3.1 ± 0.3 ka) and *Gaumukh2* (1.5 ± 0.3 – 1.2 ± 0.3 ka) debris-flow fans in Garhwal have fan surfaces dating to the Mid–Late Holocene, at a time of increasing aridity and relative cooling (Gasse et al., 1996; Fleitmann et al., 2003, 2007; Dykoski et al., 2005; Wang et al., 2005; Herzsuh et al., 2006; Hu et al., 2008; Dong et al., 2010; Leipe et al., 2014; Rawat et al., 2015; Hudson et al., 2016; Srivastava et al., 2017; Fig. 6). These conditions are the result of a decline in monsoon intensity and the strengthening of the mid-latitude westerlies due to cooling in the North Atlantic (Clift et al., 2012; Leipe et al., 2014). Local glacial stages are recognized ~ 1 – 2 ka before the stabilization and abandonment of these surfaces; *Rilkot1* postdates the m_2 stage (4.4 ± 0.1 – 1.9 ± 0.3 ka) and *Gaumukh1* and *Gaumukh2* follow the Shivling (~ 5.2 ka) and Gangotri (~ 2.4 – 1.9 ka) stages, respectively (Sharma and Owen, 1996; Barnard et al., 2004b; Srivastava, 2012). Srivastava et al. (2017) argue that the prevailing cold and dry conditions were punctuated by short-term warm-wet periods between ~ 5.4 and 3.8 ka. The Garhwal fans are therefore likely to have evolved during these periods of glacial advance or enhanced temperature and precipitation, before being abandoned thereafter.

The *Qf_SARAI* debris-flow fan surface (7.8 ± 1.2 – 2.8 ± 0.3 ka) in the Kullu valley was also abandoned during this period of increasing aridity and relative cooling in the Mid–Late Holocene (as referenced above). Although no local glacial stages have been recognized south of Pir Panjal at this time, the Sarai source catchment preserves a succession of moraines from past glacial advances (Owen et al., 2001). Studies have shown that an enhancement in the strength of the monsoon during the late glacial and Early Holocene caused glaciers to advance along the southern Himalayan front (Owen et al., 2001; Bookhagen et al., 2005; Saha et al., 2018). The evolution of *Qf_SARAI* is likely, in part, affected by this glaciation.

The spread in ^{10}Be ages for the Qf_{SARAI} is likely the result of inheritance, which is a particular problem when dating young fan surfaces and/or those composed of older reworked sediment (Gosse et al., 2003; Wittmann and von Blanckenburg, 2009; Owen et al., 2011; Blisnuik et al., 2012; Hedrick et al., 2013). Boulder weathering, exhumation, toppling and shielding by sediment, snow or ice also affects the ^{10}Be inventory of a boulder surface, producing exposure ages younger than the timing of its emplacement on the landform's surface. These geological factors and other post-depositional landform disturbance by slope processes, fluvial reworking or anthropogenic activity can produce a distribution of ^{10}Be ages on an individual fan surface.

The Qf_{SISSU} (10.9 ± 0.8 – 2.4 ± 0.3 ka) and Qf_{TELING} (11.8 ± 1.7 – 0.6 ± 0.1 ka) debris-flow fans in the Chandra valley have a broad range of fan surface ages from the Early to Late Holocene (Fig. 6). During the last glacial maximum (LGM: 24–18; Mix et al., 2001), a large ~200-km-long, 400–600 m thick glacier occupied the Chandra valley and tributaries. Deglaciation of the valley extended from ~19–16 ka (Euguster et al., 2017). Qf_{SISSU} and Qf_{TELING} formed after this glacier retreat; the older ^{10}Be ages (Qf_{SISSU} : 10.9 ± 0.8 ka; Qf_{TELING} : 11.8 ± 1.7 ka) likely contain inheritance from the LGM. The remaining Late Holocene ages indicate that the fans were abandoned during the continued decline in relative temperatures and humidity throughout the epoch. The Teling catchment is glaciated in the present day, but both catchments retain evidence of past glacial advances. The Chandra valley fans likely formed and/or evolved in response to local glaciation.

The broad distribution of ^{10}Be ages for the Karzok valley alluvial fans (Qf_{MENTOKa} : 110.8 ± 5.5 – 64.5 ± 2.9 ka; Qf_{MENTOKb} : 66.1 ± 3.6 – 12.6 ± 0.7 ka) might reflect either single or multiple phases of fan surface stabilization and abandonment during the late Pleistocene (Fig. 6). We argue that the landforms were abandoned during single events and that the range in ^{10}Be ages is

the result of inheritance, due to the lack of an exposure age gradient evident across the fan surfaces. Local geomorphic studies confirm that geological materials may contain inherited ^{10}Be due to the preservation of old landforms and sediment, and low rates of landscape change in the semi-arid western Himalaya (Hedrick et al., 2011; Dortch et al., 2011b; Orr et al., 2017, 2018). The stable position and lack of weathering features for the Men_F04 boulder suggests that the young 12.6 ± 0.7 ka age for Qf_{MENTOKb} is due to the recent exhumation of the boulder. The timing of Karzok fan abandonment extends across times of fluctuating climatic conditions (Fig. 6). Several local glacial stages including Kar_M1 (132.5 ± 36.8 ka; Saha et al., 2018) and KM1–3 (72.0 ± 31.0 ka; Hedrick et al., 2011; Dortch et al., 2013) may have contributed to the formation of this extensive bajada, however the causes of fan stabilization and abandonment remain unclear.

The *Tangtse1* debris-flow fan formed after the most recent glaciation of the Tangtse valley at 35.8 ± 3.0 ka (Brown et al., 2002, 2003; Dortch et al., 2011c; Fig. 6). The fan surface ages have a bimodal distribution; the older ages (45.1 ± 4.7 – 32.2 ± 2.6 ka) are likely the result of inheritance from this previous period of glaciation, or earlier. The remaining exposure ages are similar in age to the local Ladakh 2 glacial stage (22.9 ± 0.7 ka; Dortch et al., 2013) and the period of reduced monsoon strength and effective moisture associated with the LGM (Fig. 6).

The *Tangtse2* debris-flow fan formed after the Pangong Tso outburst flood at 11.1 ± 1.0 ka, which was a large flood event that reworked the majority of the landforms and sediment deposits that occupied the Tangtse valley floor at that time (Dortch et al., 2011c). The late-glacial ages for the fan surface therefore reflect inherited ^{10}Be . The remaining ^{10}Be ages suggest that *Tangtse2* was abandoned during the cooling temperatures and increasing aridity of the Mid–Late Holocene (Fig. 6).

Fan surface abandonment throughout the NW Himalaya

The Mid–Late Holocene fan surfaces of this study are predominantly limited to the debris-flow fans of the MWHR region. The SWHR region presents greater complexity, with the preservation of fan surfaces with abandonment ages from 110.8 ± 5.5 to 2.1 ± 0.3 ka. Preservation bias favors Holocene aged fan surfaces in the MWHR because elevated rates of erosion in this region rapidly rework and overprint landforms and sediment deposits over timescales of 10^4 – 10^1 years (Gabet et al., 2004; Wulf et al., 2010; Murari et al., 2014). The lower rates of landscape change in the semi-arid interior ranges help to preserve a longer fan record (Dortch et al., 2011a,b; Dietsch et al., 2015; Jonell et al., 2018).

The source catchments of the debris-flow fans of this study have mean slopes $>30^\circ$, above which slopes are unable to securely retain regolith, snow or ice (Table 2). The steep topography of these catchments is conducive to diffusive hillslope processes, as well as stochastic high-magnitude mass-wasting events (Gruber and Haerberli, 2007; Dortch et al., 2009; Nagai et al., 2013). The narrow valley floor and steep relief hillslopes of the Chandra valley restrict the extent to which the Qf_{SISSU} and Qf_{TELING} can aggrade out into the trunk valley. The fans are further truncated and dissected by the Chandra River and tributaries. In contrast, the Karzok valley tributary catchments which are of comparable size to the former, have shallower mean slopes ($<20^\circ$) and channel profiles (10°), which allow for large, gently sloping ($<8^\circ$) alluvial fans to aggrade throughout the valley (Table 2). These examples demonstrate the importance of topography in determining the type, size and morphology of fans in the NW Himalaya.

With the exception of the Karzok fans, the timing of fan abandonment throughout the NW Himalaya coincides with periods of relative cooling and increasing aridity (Fig. 6). During warm, wet conditions, fans aggrade and evolve as sediment is released and then transferred throughout the catchments. As the climate then transitions to cooler and drier conditions, aggradation ceases

or becomes more restricted, and the fan surface stabilizes. Fans can also develop in response to single high-magnitude events such as storms and outburst floods or rapid fluctuations in precipitation (10^4 – 10^2 years; Hasnain 1996; Craddock et al., 2007; Wulf et al., 2010).

The fan surface ages coincide with one or more local glacial stages and between one and five regional glacial stages (Fig. 6). Periods of late Quaternary glaciation throughout the Himalayan-Tibetan orogen were cooler and drier than the present day (Burbank et al., 2003). Our study therefore proposes that fans evolve during interglacial periods or phases of deglaciation during a higher intensity monsoon, and then as glacial conditions become reestablished, the fans stabilize. As an example, fan aggradation, which includes the MWHR fans of this study, occurred in the NW Himalaya as part of the landscape response to a period of glacier retreat during the Mid-Holocene. This more restricted glaciation followed a time of extensive glacial advances during the Early Holocene, which has been argued to be the result of the northerly migration of the ITCZ and an enhanced summer monsoon (Fleitmann et al., 2003, 2007; Dykoski et al., 2005; Wang et al., 2005; Herzschuh, 2006; Hu et al., 2008; Leipe et al., 2014). Enhanced cooling due to the strengthening of the mid-latitude westerlies by the Mid-Holocene likely caused a reduction in fan sedimentation and the stabilization and abandonment of fan surfaces. This example highlights the sensitivity of fans in the NW Himalaya to glacial advances and/or associated shifts in local-regional climate.

The nature and timing of fan evolution and abandonment in the NW Himalaya is determined by the interaction between climate and internal catchment dynamics such as topography, sediment supply and catchment lithology. Seismic events or shifts in base level are additional external forcing which may prompt further mass redistribution in these high-altitude settings (Owen et al., 1996; Hopley et al., 2010).

Regional records of landform abandonment and incision

The regional timing of landform abandonment for the SWHR and MWHR broadly accompany periods of weakening monsoon and relative cooling (Gasse et al., 1996; Fleitmann et al., 2003, 2007; Dykoski et al., 2005; Wang et al., 2005; Herzschuh et al., 2006; Hu et al., 2008; Dong et al., 2010; Leipe et al., 2014; Rawat et al., 2015; Hudson et al., 2016; Srivastava et al., 2017; Fig. 6). This suggests that on the regional scale, landforms aggrade and evolve during warm and wet conditions before a shift to cool arid conditions forces the stabilization and abandonment of the landforms. Regional incision events are less straightforward, as they are recognized across various climatic conditions. The ubiquitous nature of erosion in these active alpine settings is perhaps the reason for this (Barnard et al., 2006b). The contrasting geomorphic regimes of the NW Himalaya causes a similar bias in the records of landform abandonment and incision in favor of Holocene events, as has been observed in the fan record of this study.

The *Qf_{TELING}*, *Gaumukh2* and *Tangtse1* fan surface ages overlap with regional events of landform abandonment for the MWHR and SWHR regions, respectively (Fig. 6). A greater correspondence is evident however between the fans of this study and regional incision events. This correlation is likely because of the greater number of incision records available in the NW Himalaya, compared to landform abandonment records. Some landform abandonment and incision events within the regions of the MWHR (landform abandonment at 1.4 ± 0.5 ka, incision at 1.0 ± 0.1 ka) and the SWHR (landform abandonment at 31.5 ± 5.1 ka, incision at 35.9 ± 5.9 ka) are synchronous. This alludes to the existence of region-scale cycles of aggradation and incision throughout the NW Himalaya. Unlike parts of the Himalaya and other mountain systems, cycles of aggradation and incision at particular intervals (i.e. 40, 100 k cycles) are not recognized in the NW Himalaya (Pratt et al., 2002; Srivastava et al., 2008; Tofelde et al., 2017)

The MWHR and SWHR regional landform abandonment and incision events each occur alongside between two and seven regional glacial stages (MWHR landform abandonment [MOHITS 1B, 1C; HH1, 2] and incision [MOHITS 1C–1K; HH1, 2, 4–7]; SWHR landform abandonment [SWHTS 2D–2F] and incision [SWHTS 1B, 1C, 2A–2D, 2F; HH2, 3] Dortch et al., 2013; Murari et al., 2014; Saha et al., 2018; Fig. 6). This overlap is anticipated due to the duration of these geomorphic events, and the number of glacial records available throughout the inherently glaciated NW Himalaya. The most significant regional incision event for both MWHR and SWHR occurs at the time of extensive glaciation at the onset and early millennia of the Holocene (Fig. 6). This incision event likely reflects enhanced glacial and fluvial erosion during this glaciation and its association phase of deglaciation. More broadly, these regional records of geomorphic change illustrate the climatic-dependence of landscape change throughout the NW Himalaya.

CONCLUSION

The timing of fan surface abandonment has been defined for ten fans in the NW Himalaya; fan surface ages range from 110.8 ± 5.5 – 64.5 ± 2.9 ka to 1.8 ± 0.2 – 0.9 ± 0.1 ka. Debris-flow fans in the Garhwal, Kullu and Lahul regions of the monsoon-influenced Greater Himalaya are largely abandoned during the Holocene. In the Ladakh region of the Greater and Tethyan Himalaya, large alluvial fans and debris-flow fans have surface ages which extend throughout the last glacial. The type, size and morphology of the fans are shown to be influenced by the topography and fluvial channel behaviors of the source catchments and trunk valleys.

Regional landform abandonment and incision events for the MWHR and SWHR are defined over the past ~ 120 ka. In the MWHR, regional geomorphic events are restricted to the Holocene, while in the SWHR they are recognized from ~ 40 ka. The fans of this study and the regional

geomorphic records present preservation bias, where elevated rates of erosion and sediment reworking in the MWHR mean that the landforms retained in these catchments are restricted to the Holocene. The lower rates of landscape change in the SWHR enable the preservation of longer geomorphic records.

The timing of fan surface abandonment for the ten fans of this study and the regional events of landform abandonment throughout the NW Himalaya accompany periods of weakening monsoon strength and relative cooling. The landforms aggrade and evolve during warm-wet conditions before a shift to cool and arid conditions forces the stabilization and abandonment of the landforms. Regional incision events are recognized across various climatic conditions throughout the late Quaternary, likely due to the ubiquitous nature of erosion in these active alpine settings.

The fan surface ages are coincident with one or more local glacial stages and between one and five regional glacial stages. Fan formation and evolution extends throughout interglacial periods and times of deglaciation, before stabilizing once cool-arid glacial conditions return. The nature and timing of the fan evolution and abandonment is determined by the interaction between internal catchment dynamics and climate. Regional geomorphic events defined for the MWHR and SWHR regions also coincide with between two and seven regional glacial stages. This further illustrates the critical role played by glaciation and glacial processes in local and regional landscape change. More broadly, this study demonstrates the importance of climate-driven processes in the sediment flux and topographic evolution of the NW Himalaya.

ACKNOWLEDGMENTS

ENO and LAO thank the University of Cincinnati for providing tuition and stipend to support this work as part of ENO's doctoral thesis and the processing of samples for ^{10}Be dating. ENO and SS thank the Geological Society of America and the Graduate Student Governance Association, University of Cincinnati for research grants to conduct fieldwork. MWC acknowledges support from NSF (EAR-1560658). We should like to thank Dr. Paul Bierman, Dr. Nick Lancaster and Dr. Alan Gillespie for their detailed, constructive suggestions and comments on our manuscript.

D) Regional glacial stages for the NW Himalaya. Himalayan Holocene (HH) stages from Saha et al. (2018), Semi-Arid Western Himalayan-Tibetan stages (SWHTs) from Dortch et al. (2013) and Monsoonal Himalayan-Tibetan stages (MOHITs) from Murari et al. (2014). E) Regional events of landform abandonment (upper) and incision (lower) for the NW Himalaya. Probability density distribution plots for the MWHR (landform abandonment = Barnard et al., 2004a,b; Scherler et al., 2015. incision = Barnard et al., 2004a,b; Bookhagen et al., 2006b; Adams et al., 2009; Dortch et al., 2011b; Dey et al., 2016) and SWHR (landform abandonment = Brown et al., 2002, 2003; Dortch et al., 2011b; Blöthe et al., 2014. incision = Leland et al., 1998; Brown et al., 2002, 2003; Seong et al., 2007; Dortch et al., 2011a, b). Fan ^{10}Be ages of this study are not included in these PDFs. F) Fan chronologies for the NW Himalaya defined by TCN dating for Ladakh, Lahul, Kullu and recalculated for Garhwal (Barnard et al., 2004a,b) and northern Ladakh (Brown et al., 2002, 2003; Dortch et al., 2011c).

Table 1. Climate and glacial records for the Kullu, Chandra and Karzok valley study areas.

	CLIMATE			GLACIAL RECORD
	Mean annual precipitation (mm)	Mean annual temperature range (°C)	Vegetation	
Kullu valley study area*	2000–3000	-4–11	Dense broad leaved, coniferous and sub-alpine forest	15.5±0.5 ka (Rhotang Pass Stage), 12.2±1.6–10.6±0.3 ka (Solang Stage; Owen et al., 2001)
Chandra valley study area†	(a) >500 (predom. >900) (b) 400–800	(a) -12–6 (b) -15–7	Alpine herbs, sedges, grasses and sub-alpine forest	15.3±1.6 ka (Batal Stage; Murari et al., 2014), 12.4±1.2 ka (Kulti Stage; Murari et al., 2014), 10.4±0.3 ka (mH3), 0.2±0.1 ka (mH1a; Saha et al., 2018) LGM deglaciation: ~20–14 ka (Euguster et al., 2016)
Karzok valley study area‡	(a) ~115 (b) 40–100	(a) -2.8–24.7	Xerophytic shrubs and grasses	311.0±8.0 ka (KM-0), 126.0±8.0 ka (PM-0), 72.0±31.0 ka (KM1-3), 47.0±12.0 ka (PM-1), 2.7±2.3 ka (PM-2), 0.3±0.2 ka (PM-3; Hedrick et al., 2011; Dortch et al., 2013) 4.9±0.3 ka (KM-4/mG2), 2.1±0.2 ka (mM2), 1.0±0.1 ka (mM1), 0.7±0.1 ka (mM1; Hedrick et al., 2011; Dortch et al., 2013; Saha et al., 2018)

*: Kullu valley: Dhundi weather station (32.2530°N, 77.1299°E, 2850 m asl; Snow and Avalanche Establishment [SASE] 1993–2001; Gusain et al., 2004), TRMM (1998–2005; Bookhagen and Burbank 2006), vegetation from Rawat et al. (2015).

†: Chandra valley: (a) Chhota Shigri weather station (32.2867°N, 77.5365°E, 3900 m asl; 1980–2005; Wagnon et al., 2007; Azam et al., 2014); (b) TRMM (1998–2005; Bookhagen and Burbank 2006), Patseo weather station (32.7538°N, 77.2610°E, 3780 m asl; Snow and Avalanche Establishment [SASE] 1993–2001; Gusain et al., 2004); vegetation from Rawat et al. (2015).

‡: Karzok valley: (a) Leh weather station (34.1800°N, 77.5800°E, 3500 m asl; CRUTEM4 1876–1990, Jones et al., 2012; Osborn and Jones, 2014); (b) TRMM (1998–2005; Bookhagen and Burbank 2006)

Table 2. Source catchment and fan metrics for the Kullu, Chandra and Karzok valley study areas.

Fan No.	CATCHMENT CHARACTERISTICS						FAN CHARACTERISTICS

*: Mean relative relief derived from 0.13km² catchment grid cells. Catchment relative relief (m): *QF_SARAI* (2276); *QF_SISSU* (2772); *QF_TELING* (2619); *QF_MENTOKa* (1642); *QF_MENTOKb* (1520)

†: Slope derived from 0.001km² catchment grid cells

‡: Strahler (1952) Hypsometric index (mean elevation- min elevation/relief)

§: Mean depth and width derived from 10 channel cross section profiles between apex and distal zone of fan.

Table 3. Fan and surface boulder descriptions for the Kullu, Chandra and Karzok valley study areas.

Fan No.	Landform description	Surface boulder description
Kullu valley		
<i>Qf_SARAI</i>	<ul style="list-style-type: none"> Slightly weathered, matrix (sand) supported bouldery gravel diamicton. No morphostratigraphically younger units or sub-lobes on surface. Overlies older fan at Palchan (Fig. 2A). Solang Nala and Beas River truncate northern margins of mid and distal zones. Sarai Nala incises into fan revealing cut banks and terraces. Shallow, sinuous ephemeral and/or abandoned channels across fan surface. Montane forests and grasslands, well-developed soils for agricultural land use. Human settlement and infrastructure across fan surface. 	<ul style="list-style-type: none"> Distributed across northern extent of fan. Anthropogenic boulder clearing evident on southern flank. Granitic, subangular-subrounded boulders (≤ 10 m; Fig. 2B,C). Tabular, well-set boulders with no landform degradation/erosion at boulder margins. Slight-moderately weathered (minor exfoliation). Rock varnish and lichen present.
Chandra valley		
<i>Qf_SISSU</i>	<ul style="list-style-type: none"> Slight-moderately weathered bouldery gravel diamicton with sandy-silt matrix. Overlies a morphostratigraphically older fan at Sissu. Small sub-lobe extends from the distal region of fan at tributary-river confluence. Chandra River and tributaries have incised, entrenched and truncated the eastern extent of fan. Alpine tundra, developed soils for agricultural land use. Human settlement and infrastructure (inc. irrigation) across fan surface (Fig. 3A). 	<ul style="list-style-type: none"> Distributed across mid-distal zones of fan. Angular-subrounded granites and siltstones (≤ 10 m). Tabular, well-set boulders with no landform degradation/erosion at boulder margins (Fig. 3B,C). Slight-moderate weathered (minor exfoliation). Rock varnish and lichen present.
<i>Qf_TELING</i>	<ul style="list-style-type: none"> Slight-moderately weathered bouldery gravel diamicton with sandy-silt matrix. Increased surface degradation on the western fan flank. No morphostratigraphically younger units or sublobes on surface. Teling Nala and Chandra River have incised and truncated the fan. Alpine tundra, developed soils for agricultural land use. Human settlement and infrastructure. 	<ul style="list-style-type: none"> Distributed across mid-distal zones of fan. Granitic angular-subrounded boulders (≤ 10 m). Tabular, well-set boulders with no landform degradation/erosion at boulder margins (Fig. 3F). Slight-moderately weathered (minor exfoliation). Rock varnish and lichen present.
Karzok valley		
<i>Qf_MENTOKa</i>	<ul style="list-style-type: none"> Surface characterized by two depositional units (upper, lower) with consistent descriptions. Moderate-highly weathered, matrix (sandy-silt) supported sandy gravel diamicton with boulders. Northeastern distal flank of fan underlies <i>Qf_MENTOKb</i>. No morphostratigraphically younger units or sub-lobes identified on fan surface (Fig. 4A). Distal zone truncated by the Karzok River. Sinuuous tributary transforms into a large braided system across fan surface. Channels are shallow, ephemeral and/or abandoned. Alpine tundra including xerophytic shrubs and grasses. Poor soil development. 	<ul style="list-style-type: none"> Distributed across mid-distal zones of fan. Boulder ridges trend down-fan at channel margins. Granitic subangular-subrounded boulders (≤ 3 m). Tabular, well-set boulders with some landform degradation/erosion at boulder margins (Fig. 4D). Moderate-highly weathered (cavernous weathering, pitting and exfoliation). Rock varnish present.
<i>Qf_MENTOKb</i>	<ul style="list-style-type: none"> Surface characterized by two depositional units (upper, lower) with consistent descriptions. Moderate-highly weathered, matrix (sandy-silt) supported sandy gravel diamicton with boulders. No morphostratigraphically younger units or sub-lobes identified on fan surface (Fig. 4A). Distal zone truncated by the Karzok River. Sinuuous tributary transforms into a large braided system across fan surface. Channels are shallow, ephemeral and/or abandoned (Fig. 4B). Alpine tundra including xerophytic shrubs and grasses. Poor soil development. Nomadic human settlement at distal zone of fan. 	<ul style="list-style-type: none"> Distributed across mid-distal zones of fan (anthropogenic boulder clearing evident in lower distal zone). Boulder ridges trend down-fan at channel margins. Granitic subangular-subrounded boulders (≤ 3 m). Tabular, well-set boulders with some landform degradation/erosion at boulder margins (Fig. 4E). Moderate-highly weathered (cavernous weathering, pitting and exfoliation). Rock varnish present.

11. Supplementary Items

11.1 Supplementary Geomorphic Maps

SI_0. Geomorphology and locations of the Kullu, Chandra and Karzok study areas (*Focus 3*). Black rectangles outline the detailed geomorphic maps shown in Fig 7. A) Kullu valley study area. B) Chandra valley study area. C) Karzok valley study area. Inset hillshade map shows the location of the study area (dashed black polygon) and the *Kar_MI* moraine (includes ^{10}Be boulder sample locations).

SI_0. cont.

11.2. Supplementary Items (Manuscript 1)

Supplementary Item 1. Adjusted ^{10}Be concentrations and interpreted bedrock slope erosion rates for the upper Bhagirathi catchment

	Medial moraine	Max. distance of debris transport ¹ (km)	Max. ^{10}Be inheritance during debris transport ²				^{10}Be inheritance during debris transport ³			
			Duration of transport (a)	^{10}Be production (10^4 at/g)	Adjusted ^{10}Be conc. (10^4 at/g)	Adjusted erosion rate (mm/a)	Duration of transport (a)	^{10}Be production (10^4 at/g)	Adjusted ^{10}Be conc. (10^4 at/g)	Adjusted erosion rate (mm/a)
G _{sup1}	<i>SD_A</i>	9	450	4.3	-3.2	-	188	0.8	0.3	18.2
G _{sup2}	<i>SD_A</i>	12	475	4.5	-3.0	-	198	0.8	0.8	7.4
G _{sup3}	<i>SD_B</i>	12.5	600	5.7	-3.1	-	250	1.0	1.7	3.4
G _{sup4}	<i>SD_B</i>	9.5	625	6.0	-3.5	-	260	1.0	1.4	3.9
G _{sup5}	<i>SD_B</i>	14.5	725	6.9	-4.3	-	302	1.2	1.4	4.1
G _{sup6}	<i>SD_C</i>	14.5	725	6.9	-5.4	-	302	1.2	0.3	18.7

1: Estimated using a SRTM DEM (30 m resolution), measuring from the highest elevation of the medial moraine to the sampling location.

2: Inheritance during transport calculated with mean production rate of 95.4 ± 12.2 at/g/a and a glacier surface velocity of 20 m/a (Bhattacharya et al., 2016).

3: Inheritance during transport calculated with a production rate of 40 at/g/a and a glacier surface velocity of 48 ± 4.8 m/a (Bhattacharya et al., 2016).

–: Estimated ^{10}Be production on medial moraine exceeds ^{10}Be concentration measured. Erosion rates are not derived.

Supplementary Item 2. Cross-sections of Gangotri medial moraines at sampling locations. Sections are referenced to the highest point in each profile. Refer to Fig. 2 for the sampling locations.

Supplementary Item 3. SEM images of Gangotri medial moraine samples. G_{sup1} i) 350x mag ii) 500x mag iii) 1000x mag. G_{sup2} i) 80x mag, ii) 350x mag, iii) 500x mag. G_{sup3} i) 120x mag, ii) 200x mag, iii) 650x mag. G_{sup4} i) 150x mag, ii) 120x mag, iii) 250x mag. G_{sup5} i) 120x mag, ii) 350x mag, iii) 500x mag. G_{sup6} i) 100x mag, ii) 200x mag, iii) 1000x mag.

Supplementary Item 4. Percentage grain size distribution of Gangotri medial moraine samples.

1: Mean horizontal distance from entry point at glacier head to ELA (measured from 20 profiles).

2: Catchment ^{10}Be production rate

3: Dimensionless slope of the glacier surface

4: Mean speed of rock particle on glacier surface

5: Spallation falloff scale in air

6: Spallation falloff scale in ice (0.65*3)

7: Initial depth of particle at entry point at glacier head

8: Accumulation of ^{10}Be between bedrock slope and medial moraine sampling location

Supplementary Item 3. P values between catchment matrices and geochemical data.

*: Topographic Shielding Factor

†: LSD age (internal/external errors quoted) is calculated using the Balco et al. (2008) calibration dataset (^{10}Be decay constant of $5.1 \pm 0.3 \times 10^{-7}$), and Lifton et al. (2014) calculation scheme with the Lifton 2016 VDM geomagnetic database. Production rate for the CREP calculator is 4.13 ± 0.2 ^{10}Be atoms/grams SiO_2 /year (Martin et al., 2016) with a ^{10}Be half-life of 1.36Ma. Density of 2.7 g cm^{-3} , AMS Standard of 07KNSTD.

Supplementary Item 4. Sample details of semi-arid western Himalayan ranges (SWHR) regional landform abandonment and incision events (uncertainties expressed as 1σ)

*: Topographic Shielding Factor

†: LSD age (internal/external errors quoted) is calculated using the Balco et al. (2008) calibration dataset (^{10}Be decay constant of $5.1 \pm 0.3 \times 10^{-7}$), and Lifton et al. (2014) calculation scheme with the Lifton 2016 VDM geomagnetic database. Production rate for the CREP calculator is 4.13 ± 0.2 ^{10}Be atoms/grams SiO_2 /year (Martin et al., 2016) with a ^{10}Be half-life of 1.36Ma. Density of 2.7 g cm^{-3} , AMS Standard of 07KNSTD.

Supplementary Item 5: Fan surface ¹⁰Be ages from available calculation schemes
